# Abstract

**Background:** The Mini-Mental Adjustment to Cancer Scale (Mini-MAC) instrument is commonly used worldwide by professionals of oncology, but the scale has not, up to date, been validated in Arabic and Moroccan context, and there is absence of data in the Moroccan population. This study aims to validate the Mini-MAC, translated and adapted to the Arabic language and Moroccan culture, in women with breast cancer.

**Methods:** The Mini-MAC instrument was administered to 203 breast cancer women, receiving medical care in the university Hospital of Fez city. A cross-sectional validation study using exploratory factor analysis and Confirmatory factor analysis was carried out.

**Results:** Confirmatory factor analysis confirmed Watson's original structure underlying the Mini-MAC items: Helpless/Hopeless, Anxious Preoccupation, Fighting Spirit, Cognitive Avoidance, and Fatalism. Absolute, incremental, and parsimonious fit indices showed a high significant level of acceptance confirming a good performance of the measurement model. The instrument showed sufficient reliability and convergent validity demonstrated by acceptable values of composite reliability (CR =0.93–0.97), and average variance extracted (AVE= 0.66 - 0.93), respectively. The square roots of AVE were higher than factor-factor pairs correlations, and the Heterotrait-Monotrait ratio of correlations values were lesser than 0.85, indicating an acceptable discriminant validity.

**Conclusions:** reliability; and both convergent and discriminant validity tests indicated that The Arabic version of the Mini-MAC had a good performance and may serve as a valid tool measuring psychological responses to cancer diagnosis and treatment.

## Background

Nowadays, Non-communicable diseases (NCDs) represent the major health challenges for developing countries; where the annual mortality rate exceeds largely that of all other diseases combined. Nearly 80% of NCDs deaths occur in low and middle-income countries (1). As one of the African middle-income countries, Morocco is experiencing a substantial increase in the burden of NCDs along with a higher mortality rate. NCDs represent approximately 75% of total deaths in the country (2).

Breast cancer is one of the most common cancers in women around the world (3) and it's the most prevalent deadly disease of women in low and middle-income countries, and pictured as a symbol of the end of life (4). It primarily concerns young women by targeting the most valuable thing in their life; the breast mirror feminine valuableness, esthetic appearance, and motherhood (5).

Breast cancer is the leading cancer with an incidence of 10,136 new cases diagnosed in 2018, representing 19.2% of the overall cancer incidence and 36.9% of cancers diagnosed in Moroccan women. In terms of mortality. It is second, after lung cancer, with 3,518 deaths, or 12.3% of total cancer deaths (6). As the magnitude of the breast cancer epidemic continues to accelerate, health-care interventions

become cost effective for health system. Aiming to maintain and deliver an effective and affordable service for sick people, Moroccan health system is embracing a package of measures in parallel with an emerging paradigm called the biopsychosocial model (7). The latter seeks to integrate the psychological and the social dimensions in the traditional biomedical model. Psychological aspects are described in terms of cognitions, emotions and behaviors, whereas social aspects consist of social norms of behavior, pressures to change behavior, social values on health, social status and ethnicity (8). Understanding these elements helps to determine the styles of psychological adjustments in cancer patients. Oncology specialists believe that coping style is very relevant in making decisions about adjuvant therapy or active follow-up, coping with side effects of treatment, and anxiety caused by uncertainty in the prognosis (9).

There are many scales to assess psychological adjustment such as "The Coping "The Ways of Coping Checklist" (WCC-R) (10), "The Coping with Health Injuries and Problems Scale" (CHIPS) (11), and The Mental Adjustment to Cancer (MAC) Scale (12).

The "Mental Adjustment to Cancer" (MAC) is a 40-item scale distributed over five subscales, and has become a widely used instrument for assessing psychological adjustment in cancer patients. Several studies have tried to validate the MAC subscales, but they were not be able to replicate the original factor structure (13,14). Hence, the original version was revised by Watson (15), leading to a 29-item scale with psychometric properties comparable to the original MAC scale. The shortened version was called the "Mini Mental Adjustment to Cancer Scale" (Mini-MAC). It consists of five scales ((Helpless/Hopeless (HH), Anxious Preoccupation (AP), Fighting Spirit (FS), Cognitive Avoidance (CA), and Fatalism (FA)).

The Mini-MAC, distilled from the MAC, has been translated into several other languages and investigated by many studies. Some authors have confirmed the original five-factor structure of the original Mini-MAC (16–19), while others proposed different structures of two (20), three (21), four (22–24) or five factors (16, 18, 19, 21, 25).

Among the five original factors, the fatalism subscale has sparked much debate among authors. Originally defined as a maladjustment style, fatalism was supposed to be adopted by patients to accept the situation as inevitable. Meanwhile, other studies (21) have considered it as an adaptive measure to religion, faith, reassessment, positive thinking, and acceptance (19, 24, 26). Fatalism was found to be positively correlated with spirituality and active participation in religious practice, but was not associated with a perceived lack of control and acceptance of results. The fatalism of Mini-MAC may be more associated with feelings of personal control and that it has a positive effect on the health of women with breast cancer (21).

Literature review reports incongruity and dissonance between authors' findings regarding the Mini-MAC's factor structure. This is due to many variables such as methodological issues, types and stages of cancer, and sample sizes. Together, these minor and major discrepancies of unstandardized studies would have been an impediment to obtaining unified and robust factor solutions (27). In addition, most validation studies of Mini-MAC scale are not well grounded, and should be taken with caution. Indeed,

though EFA is discouraged to draw substantive conclusions from a scale structure (28), few studies have conducted CFA to investigate the validation of the Mini-MAC scale (18, 22, 29).

The Mini-MAC instrument is commonly used worldwide by professionals of oncology, but the scale has not, up to date, been validated in Arabic and Moroccan context, and there is absence of data in the Moroccan population. To this end, the present study aims to examine the factor structure, the reliability and validity of the Mini-MAC among the breast cancer women in Morocco. In this line, to test the five first-order latent factors of the Mini-MAC original version, structural equation modeling using CFA was undertaken.

## **Methods**

### **Mini-MAC Scale translation**

The original version of Mini-MAC scale was translated from English to Arabic, then reviewed by an expert group, and finally translated back into English by two independent translators who are unfamiliar with the Mini-MAC scale. Back translation was checked by English experts and corrected on the basis of comments. After it was estimated as satisfying, the committee decided on the final Arabic version. The latter was then pilot tested, asking 20 breast cancer women to complete and comment on the questionnaire. No item was noticed to be difficult to understand, or confusing. Hence, no revision was made after the pilot test.

### **Participants and Procedure**

A consecutive series of breast cancer women attending routine follow-up appointments at a public oncology hospital in Fez city were recruited. Participants in this study were included based on inclusion criteria: diagnosed with a histologically confirmed breast cancer, aged 18 years or above, able to read Arabic adequately, mentally and physically fit, and aware of their cancer diagnosis. To measure the coping styles of patients with cancer, the recruited women were interviewed to fill the Mini-MAC questionnaire, and their demographic and clinical characteristics were collected. All the participants were notified about the aim of the study; their written approval to answer the questionnaires was given, and was approved by the bioethics committee of the Hassan II hospital.

### **Measures**

Mini-Mental Adjustment to Cancer Scale (Mini-MAC) consists of 29 items on a four-point Likert scale ranging from "Definitely does not apply to me" to "Definitely applies to me". It assesses five cognitive subscales: helpless/hopeless (HH, 8 items), anxious preoccupation (AP, 8 items), fighting spirit (FS, 4 items), cognitive avoidance (CA, 4 items), and fatalism (FA, 5 items). In phase 1, the 29-item Mini-MAC (original version) was piloted with 158 breast cancer women between February 2018 and April 2018. In phase 2, the modified 24-item Mini-MAC instrument (version 2) was distributed to 203 breast cancer women between Mai 2018 and July 2018.

# Statistical analyses

Statistical data analyses were performed on R program with packages “psych”, “semTools”, and “lavaan”. Mini-MAC items on the whole sample was first analyzed by descriptive statistics. Then, the structure and internal consistency of the Mini-MAC questionnaire were tested. The suitability of the correlation matrix was verified, to ensure that it is factorized, based on the Kaiser–Meyer–Olkin (KMO) test and the Bartlett sphericity test (30). The factorial structure of the Mini-MAC instrument was examined on the first sample (N = 158) using Exploratory Factor Analysis (EFA). The violation of the assumption of multivariate normality was assessed by Mardia’s test (31). To determine the appropriate number of factors to extract, and due to the skewed ordinal, parallel analysis of polychoric correlations with PCA as a method of extraction was performed (32). Whereas, the EFA was done by principal axis factoring (PAF) as extraction method and oblimin rotation. To get the most parsimonious factor structure, the items with low communalities (less than 0.20), the significant cross-loaded items, and the unrepresentative ones were eliminated from the analysis. This was performed in a stepwise fashion; and the EFA was rerun after each step (33). The reliability of the Mini-MAC Scale was assessed based on its internal consistency, by determining Cronbach’s alpha coefficient. The theoretical model of the Mini-MAC instrument was validated by confirmatory factor analysis (CFA). A 24-item confirmatory factor analysis was conducted on the whole sample (N = 203) using item-level ordered categorical data because items level of measurement is ordinal. Hence, CFA was performed using a polychoric correlation matrix and diagonal weighted least squares (DWLS) robust estimation technique. The measurement model was assessed by composite reliability (CR) and average variance extracted (AVE) to demonstrate internal consistency and convergent validity, respectively. Discriminant validity was tested through Fornell-Larcker criterion and Heterotrait-Monotrait (HTMT) ratio (34). The Fitness of the measurement model was reported from three categories of incremental fit (CFI, IFI, AGFI); 2) absolute fit (RMSEA, GFI), and 3) parsimonious fit (Chisq/df).

## Results

### Sample Characteristics

Two hundred three breast cancer patients agreed to participate in this study. The average age of the population was  $48.86 \pm 11.65$  with extremes of 26 and 88 years. 68% of the patients were married and 59.6% were housewives. Concerning the level of study, 67.5% were illiterate and only 3.9% followed higher education. According to their living environment, 41.4% of the patients lived in rural areas. Cancer staging yields 50.2%, 18.7% and 29.1% respectively for stages II, III and IV (Table 1).

## Exploratory factor analysis

The underlying factor structure of the Mini-MAC was examined by analyzing the data from the first random sample ( $n = 158$ ). The sampling adequacy for performing the analysis was verified through the Kaiser–Meyer–Olkin test (KMO). The total KMO value was .89, and all KMO values for individual items were  $> .67$ , well above the acceptable limit of .60 (35). Bartlett’s test of sphericity ( $\chi^2 = 3188.57$ ,  $df = 406$ ,  $p = .000$ ) indicated that inter-item correlations were sufficiently large to perform EFA.

Parallel analysis of polychoric correlation with PCA as a method of extraction and Velicer MAP criterium supported the adequacy of a five-factor solution. Factorial analysis with Principal axis factoring (PAF) as extraction method and oblimin rotation has yielded the first structure resembling nearly the authentic Mini-MAC version (Table 2). A loading cutoff point of at least 0.30 was initially used. Items that failed to load higher than this threshold or loaded significantly onto multiple factors were rejected from all factors. After each run, the analysis of the rotated factor matrix showed the significant factor loadings and the changes in communalities values. If an observed variable was not significant, it was eliminated from the measurement model. In each case that a variable was dropped, the model was respecified and run again. This was done over multiple iterations until a structured rotated factor matrix was found and communalities of all remaining observed variables were greater than 0.20.

Accordingly, Items 3, 9, 22 and 27 cross-loaded significantly onto two different factors, and were thus dropped from this model. Item 25 was removed because it failed to load significantly onto any factor. Despite the loss of five items in the factorial composition, the refined model replicated the five factors structure of the original version of Mini-MAC subscales (Helpless/Hopeless, Anxious Preoccupation, Fighting Spirit, Cognitive Avoidance, and Fatalism). The current five factors were constituted of the items making up the original scales. Hence, the factor names were maintained, and the five-factor model (model 1: HH, AP, FS, CA FA) was then assessed by CFA. The five factors, with eigenvalues between 1.62 and 4.26, and composed of 3 to 7 items, explained a total variance of 63% (Table 2).

Table 2

### Internal consistency

The reliability of the Mini-MAC Scale was assessed based on its internal consistency, by determining Cronbach’s alpha coefficient. Cronbach’s alpha and item–total correlations (corrected) were calculated for each construct and statement item, respectively (Table 2). The Fatalism construct showed a minimum alpha value of 0.71, the remaining subscales exhibited alpha values between 0.88 and 0.94, which confirmed a very good internal consistency. The alpha values needs to be at least 0.70 and ideally above 0.80 to be considered as a good consistency. This meant that all constructs were reliable.

The minimum item-total correlation calculated was 0.50. The threshold for item–total correlations should be greater than 0.30 (30). Table 2 illustrates that all of the constructs and statement items were unidimensional and had sufficient and acceptable internal consistency.

### Confirmatory factor analysis

#### Interscale correlations

The highest and most significant correlations ( $p < 0.001$ ) were observed within two groups of factors, termed maladjustment (HH and AP) and positive adjustment (FS, CA and FA) factors. Factors pertaining to the same group, either adjustment or maladjustment one, correlated positively with each other. However, the correlations between the factors of the two groups correlated negatively ( $r = -0.03$  to  $-0.70$ ). FS, CA, and FA correlated negatively with HH and AP ( $r = -0.03$  to  $-0.65$ ), but correlated positively with each other ( $r = 0.43$ – $0.77$ ). AP showed a moderate negative correlation with Fatalism ( $r = -0.42$ ,  $p < 0.001$ ) and Fighting Spirit ( $r = -0.40$ ,  $p < 0.001$ ), and insignificant correlation with CA ( $r = -0.03$ ,  $p = ns$ ). FS shows a high and positive correlation with Fatalism ( $r = 0.77$ ,  $p < 0.01$ ), and a moderate and positive correlation ( $r = 0.43$ ) with CA. On the other hand CA and Fatalism have a positive significant correlation ( $r = 0.56$ ) (Table 3).

### Convergent validity

The first-order confirmatory factor analysis results also showed that the standardized regression coefficients exceeded 0.60; the smallest factors loadings (0.61) occurred at AP factor (item AP15). The remaining 23 factors were all greater than 0.70. In addition, the t-ratio (A t value is calculated by dividing the parameter estimate by the standard error) associated with each factor-factor pair and factor-variable pair exceeded 1.96, which indicated a significant relationship with a p-value less than 0.05. With the regression coefficients greater than 0.50 and the significant relationships associated with the high t-scores indicated that the first-order confirmatory factor analysis had statistically obtained convergent validity (30) (Fig. 1).

As the result of the CFA (Fig. 1), the structure of the hypothesized model of the 24-item Mini-MAC instrument was confirmed. The reliability and convergent validity of the instrument were also asserted, with high values for the CR (0.93–0.97), and AVE values > 0.50 (0.66–0.93), respectively. That is, the whole process of factor analysis was confirmed, and the Mini-MAC instrument fitted the data fairly well (Table 3).

Table 3  
Composite reliability, average variance extracted, maximum and average shared variance, and correlations between constructs

Latent Constructs	CR	AVE	MSV	ASV	Latent Constructs				
					1	2	3	4	5
1. Helpless-Hopeless	.95	.75	.62	.41	<b>.86</b>				
2. Anxious Preoccupation	.93	.66	.62	.24	.79 <sup>a</sup>	<b>.81</b>			
3. Fighting Spirit	.97	.89	.59	.41	-.70 <sup>a</sup>	-.40 <sup>b</sup>	<b>.94</b>		
4. Cognitive Avoidance	.97	.93	.41	.20	-.30 <sup>b</sup>	-.03	.43 <sup>b</sup>	<b>.96</b>	
5. Fatalism	.93	.82	.59	.38	-.65 <sup>a</sup>	-.42 <sup>b</sup>	.77 <sup>a</sup>	.56 <sup>b</sup>	<b>.90</b>
b $p < 0.01$ ; a $p < 0.001$									
CR, Composite reliability; AVE, the square root of the average variance extracted; MSV, Maximum Shared Variance; ASV, Average Shared Variance									

### Discriminant Validity, Fornell and Larcker criterion

In Table 3, the bolded values are square root of Average Variance Extracted (AVE) of each dimension, whereas other values are inter-correlation among the latent factor dimension. The highest correlation value between factors was 0.79 (between HH and AP), while the smallest value among the square root of AVE values was 0.81. The findings warranted the discriminant validity of all model factors, since the matrix diagonal values were higher than the off-diagonal values in the corresponding rows and columns. Average Shared Squared Variance (ASV) and Maximum Shared Squared Variance (MSV) were less than

Average Variance extracted (AVE). HTMT value that is lesser than .85 or .90 (36), indicates a good discriminant validity. It appears from Table 4 that all matrix values are below 0.85, which plead in favor of a confirmed discriminant validity between all constructs of the proposed model. Overall, reliability and both convergent and discriminant validity tests indicated that the proposed constructs of measurement model were justified.

Table 4  
Discriminant validity analysis : Heterotrait-monotrait (HTMT) criterion results

	<b>Helpless-Hopeless</b>	<b>Anxious Preoccupation</b>	<b>Fighting Spirit</b>	<b>Cognitive Avoidance</b>	<b>Fatalism</b>
Helpless-Hopeless	1				
Anxious Preoccupation	.76	1			
Fighting Spirit	.52	.30	1		
Cognitive Avoidance	.19	.06	.48	1	
Fatalism	.49	.29	.61	.35	1

### **Fitness of the measurement Model**

Evaluating the first-order measurement model included calculating the goodness-of-fit statistics and the standardized regression coefficients from the standardized model. The fit statistics for the first-order measurement model were  $\chi^2 = 225$  ( $p = 0.77$ ), root mean square error of approximation (RMSEA) = 0.040, Goodness of Fit Index (GFI) = 0.99, adjusted goodness of-fit index (AGFI) = 0.98, and comparative fit index (CFI) = 0.98, normed fit index (NFI) = 0.98, and Chi -square/ degrees of freedom ( $\chi^2/df$ ) = 0.93 (Table 5).

The fitness of first order model was assessed by three categories of fit statistics: absolute fit, parsimony correction, and incremental indices. These goodness-of-fit measures were highly acceptable when following the threshold values for fit statistics: the  $\chi^2/df$  should be less than 3, CFI should be greater than 0.95, NFI should be greater than 0.90, AGFI should be greater than 0.90, and the RMSEA should be less than 0.05 (30, 37). Based on these ranges, all values were within acceptable threshold values. Therefore, the measurement model showed a good fit for the observed variables and relational contracting norm latent factors.

Table 5  
Overall fit indices of the CFA model

Fit index	Absolute Fit			Incremental Fit			Parsimonious Fit
	$\chi^2$	RMSEA	GFI	AGFI	CFI	NFI	$\chi^2/df$
Observed Value	242	.040	.99	.98	.98	.98	.93
Level of acceptance	p = .77 p > .05	< .05	> .90	> .90	> .90	> .90	< 3

RMSEA, root mean square error of approximation; GFI, goodness of fit index ; AGFI, adjusted goodness of fit index; CFI, Comparative fit index; NFI, normed fit index,,  $\chi^2$ , Chi-squared test; df, Degrees of Freedom

## Discussion

The major purpose of this work was to develop an Arabic version of the Mini-MAC instrument useful among Moroccan population. To this end, a sample of 203 breast cancer women was investigated using exploratory and confirmatory factor analysis. After dispatching five items, the current version was validated yielding the five-factors structure of the original version of Mini-MAC instrument (Helpless/Hopeless, Anxious Preoccupation, Fighting Spirit, Avoidance, and Fatalism). The same structure, proposed originally by Watson et al, has been already validated by many authors working on different types of cancer (15–19, 21). Our validated version showed similar psychometric properties as the original version (15), and other Mini-MAC validated version (17, 19, 22–24).

The only difference between previous findings and ours resides in the degree of factors reliability and the factor intercorrelations. In this study, the coefficients reliability for AP, FS, CA and FA are significantly high compared to some previous studies (15, 17, 18, 24), but seem nearly similar to certain others (19, 25).

The factors belonging to the group of passive coping strategies or maladjustment (HH/AP) are positively correlated with each other, but negatively correlated to those belonging to the group of active coping strategies or adjustment (FS, CA, and FA), and vice versa. This contradicted the original study (15), but corroborated that of Patoo et al's study (19) who reported the same trend of correlation between these factors. CA showed a significant positive correlation with FS as well as with FA. Only the second association was pointed out in the original study (15), while the same results was reported by other studies (17, 18, 21, 24). In line with Watson et al's work (15), our findings also showed a mild negative correlations between CA and AP; and a high negative correlation between CA and HH. The latter correlation was reported only by Patoo, Allahyari (19) who showed a mild negative correlation between the two factors. Indeed, these results, and in contrast to most previous studies, suggest that CA is an indicator of positive adjustment, and is positively associated with FS and FA. Nevertheless, many authors consider CA as an active distraction strategy that may facilitate problem-focused coping (19, 21, 26).

Some studies have grouped Mini-MAC factor adjustment to cancer into two types of strategies: passive coping strategies (Fatalism, Anxious Preoccupation and Helpless/Hopeless), and active strategies (Fighting Spirit and Cognitive Avoidance) (16, 38). However, this is not the case for the current study, where fatalism, and Cognitive Avoidance were found as positive coping styles (19, 21), and not a maladjustment as it is stated by some authors (18, 22). Besides, Chinese study has divided Mini-MAC subscales into two groups called Negative and Positive Emotions. The first one, an indicator of maladjustment, includes Anxious Preoccupation and Hopelessness, whereas the second, indicator of positive adjustment, includes Fatalism and Fighting Spirit. The positive emotion group was found significantly associated with Cognitive Avoidance (21).

Fatalism showed a negative correlation with the factors of the passive coping strategies, and a positive correlation with those of the active strategies. These findings corroborated some studies (18, 19, 24, 26), and at the same time contradicted others (16, 17, 22).

In contrast to western countries, Fatalism is considered as a positive coping strategy in Moroccan culture, the same results have been found in a Persian, Korean and Chinese countries (19, 21, 24). Of particular note, Moslem people found their faith on destiny and fatalism, which has a different connotation from western countries; fatalism means acceptance and satisfaction based on the person's reasons first, and then trust in God. That means positive attitude gathering fatalism with fighting spirit. These findings are consistent with those of Islamic (19) and Asiatic versions (21, 24, 26) while they contrast with most western countries (16–18, 22). They have asserted that Fatalism represents a positive adaptation and psychological battle with cancer. Our findings confirm the previous argument that FA is an adaptive coping tendency having no correlation with distress (24, 25).

These interpretations should consider some caveats concerning methodological issues. In this light, most previous studies of Mini-MAC validation are based on exploratory factor analysis, which makes them less reliable (15, 17, 19, 21–25). Whereas few studies are grounded on confirmatory factor analysis (16, 17, 26). Additionally, the factor structure reported by different unstandardized studies should be variant due to many variables such as the type of cancer, sample size, culture, age, gender, patients, and phases of cancer. To deduce well grounded conclusions about the reliability and validity of the Mini-MAC instrument for its future application, both analyses were adopted in the current study. The fivefactor measurement model showed an excellent fit according to the cut-off values of Absolute, incremental and parsimonious fit indices. The validity and reliability aspects were considered based on CFA outputs, and the fitness indices were supported by strong literature being referred (30).

However, this study has some limitations that should be highlighted. The sampling was conducted in a single regional hospital, and targeted a small sample size of cancer patients with specific type of cancer. In addition, the sample is small, and contains patients with different age range; cancer stages of disease, receiving different medical care at one Hospital. Hence, these findings cannot, however, be extrapolated to all Moroccan cancer patients from different regions. Thus, more inclusive studies should be performed,

while taking into account these variables. Moreover, longitudinal survey are needed to assess the predictive validity of the scale for psychosocial outcomes.

This shorten version of 24 items is a quick, valid, and reliable instrument in assessing cancer-specific coping of the adjustment response to cancer. It will allow physicians to know how negative and positive psychological adjustment to the illness could affect clinical practice. Hence, the acceptable psychometric properties obtained in this Arabic Mini-MAC guarantees its future use in clinical practice to measure various coping responses of breast cancer women.

## Conclusions

Overall, this work represents the first validation of the Arabic version of the Mini-MAC instrument. We investigated its psychometric properties among a sample of 203 Moroccan breast cancer women and used SEM to examine its factor structure. Our findings demonstrate that this version of five factor structure showed a good performance and is likely to serve as a valid instrument for examining cancer-coping styles and mental adjustment of cancer patients.

## List Of Abbreviations

AGFI: adjusted goodness of-fit index;

AP: Anxious Preoccupation;

ASV: Average Shared Variance;

AVE: square root of the average variance extracted;

$\chi^2$ / df: Chi square value/degrees of freedom;

CA: Cognitive Avoidance;

CFA: Confirmatory factor analysis;

CFI: comparative fit index;

CFI: Bentler Comparative Fit Index;

CR: Composite reliability;

EFA: exploratory factor analysis;

FA: Fatalism; FS: Fighting Spirit;

GFI: Goodness of Fit Index;

HH: Helpless/Hopeless;

HTMT: Heterotrait-monotrait criterion;

Mini-MAC : Mini Mental Adjustment to Cancer;

MSV: Maximum Shared Variance;

NFI: normed fit index;

RMSEA: Root mean square error of approximation.

## **Declarations**

### **Ethics approval and consent to participate**

Ethical approval was obtained from the hospital-university ethics committee of Sidi Mohamed Ben Abdellah University (N° 24/18). All the participants were notified about the aim of the study and had provided a written consent before starting the investigation.

### **Consent for publication**

Not applicable.

### **Availability of data and materials**

The datasets used and analyzed during the current study are available from the corresponding author on reasonable request.

### **Competing interests**

The authors declare that they have no competing interests.

### **Funding**

The Research reported in this publication was supported by Moffitt Cancer Center under the NIH International Fogarty Center for the award number 5D43TW009804, PI Anna Giuliano.

### **Authors' contributions**

MER has been involved in the the conception and design of the study, acquisition of data, analysis and interpretation of data, and drafting the manuscript; JE has carried out the statistical analysis, interpretation of data, and drafting the manuscript; LA has contributed to the conception and design of the study, and acquisition of data; AE has contributed to the conception and design of the study, and acquisition of data; MO has been involved in the acquisition of data; MA has contributed to the

conception, and design of the study; ZB has contributed to the conception and design of the study, and acquisition of data; NM has contributed to the acquisition of data; KE has contributed to the conception and design of the study, KH has contributed to the conception and design of the study, BZ has contributed to the conception and design of the study, and the acquisition of data, has been involved in revising the manuscript critically, and has given the final approval for the paper to be published. All authors read and approved the manuscript.

## Acknowledgements

We are grateful to all the patients who participated in the study. We also thank all the health professionals working in Hassan II University Hospital of Fez who helped us to recruit the participants needed for our study.
