22 **Abstract**

23 **Background:** Intensification of agricultural systems may result in overexploitation of  
24 water resources in arid regions because enhanced productivity of crops is often  
25 associated with increased actual evapotranspiration (AET). The aim of this study was  
26 to quantify the effect of increased regional AET on the groundwater level in a case study  
27 of the oasis located within the Shiyang River Basin near the edge of the Gobi Desert.

28 **Result:** The results of the study show that regional AET increased during the period  
29 from 1981 to 2010 due to increasing oasis area and air temperature. The water losses  
30 due to AET exceeded the water supply from the mountainous discharges of the basin  
31 by the end of this period, leading to groundwater overexploitation in the oasis area.

32 **Conclusions:** This case study shows the importance of considering the effect of climate  
33 change on water losses associated with increasing agricultural production for the  
34 sustainable agricultural development of arid regions.

35 **Keywords:** Oasis water utilization, regional AET, groundwater responses, Shiyang  
36 River Basin

## 38 **Background**

39 Anthropogenic modifications have had substantial influences on natural earth  
40 systems in past centuries. For example, agricultural development has led to a significant  
41 impact on water-soil exploitation [1], resulting in remarkable variations in regional  
42 ecohydrology and the availability of water resources in many parts of the world [2-6].  
43 Today, human beings are facing a series of water-related challenges, including the need  
44 to meet growing requirements for food production, human health, environmental safety,  
45 and so on [7-8]. The inherent requirement of water resources for socioeconomic  
46 development, especially in arid or semiarid regions, has caused river exploitation to  
47 reach capacity [9], resulting in deterioration of the river systems and groundwater  
48 systems [10-12], as well as degradation of land surface ecology [13-14]. Specifically,  
49 inland river basins in northwestern China have experienced prosperous periods over the  
50 past thousands of years when the availability of water was adequate for a limited  
51 amount of agriculture and grazing [15]. The balance of supply and demand in many  
52 natural-artificial water systems in this region has sharply tipped in recent decades due  
53 to rapid population growth and oasis scale expansion [16-17]. The original nature of  
54 river-groundwater exchange in the middle and lower parts of the basins was changed  
55 by division/storage projects and groundwater pumping. Artificial procedures have  
56 greatly altered the natural horizontally dominated slower water movement [18] into  
57 vertically dominated faster processes in irrigated areas [19-20]. Water availability could  
58 not match the speed of consumption. Stresses of continuously increasing utilization

59 have inevitably resulted in general water overexploitation in critically water-scarce  
60 areas [21-23].

61 From the perspective of water balance in inland river basins, mountainous discharge  
62 maintains the existence of natural oases, artificial oases and groundwater systems [24-  
63 25]. On the one hand, due to the arid climate and intensive evapotranspiration, rare  
64 precipitation cannot form locally effective recharge for the groundwater system in the  
65 plain area of the inland river basin [26]. On the other hand, desert vegetation is  
66 significantly affected by local precipitation, while oasis water consumption for  
67 vegetative productivity is mainly supported by mountainous discharge and groundwater  
68 [27]. With the continuous expansion of the oasis scale and the increasing consumption  
69 of water for industrial and life purposes, water resources from mountains have gradually  
70 become insufficient, and local areas have to exploit groundwater to meet the increasing  
71 water requirements [28]. Based the above information, surface runoff development  
72 leads to a decrease in supplies, and groundwater abstraction reduces reserves, both of  
73 which contribute to rapid groundwater system degradation [29].

74 Quantification of the ecological-environmental processes that involve water in arid  
75 regions is essential for understanding and planning local development. However, errors  
76 in data collection regarding water utilization may result in significant uncertainties in  
77 analyses. Fortunately, land surface processes, such as variation in greenness and AET  
78 monitored by satellite sensors, as well as their derivations, satisfactorily represent  
79 reality [30], e.g., classification of land use/cover types in a satellite image could be a  
80 key to determining hydrological variables, such as AET, for evaluation of

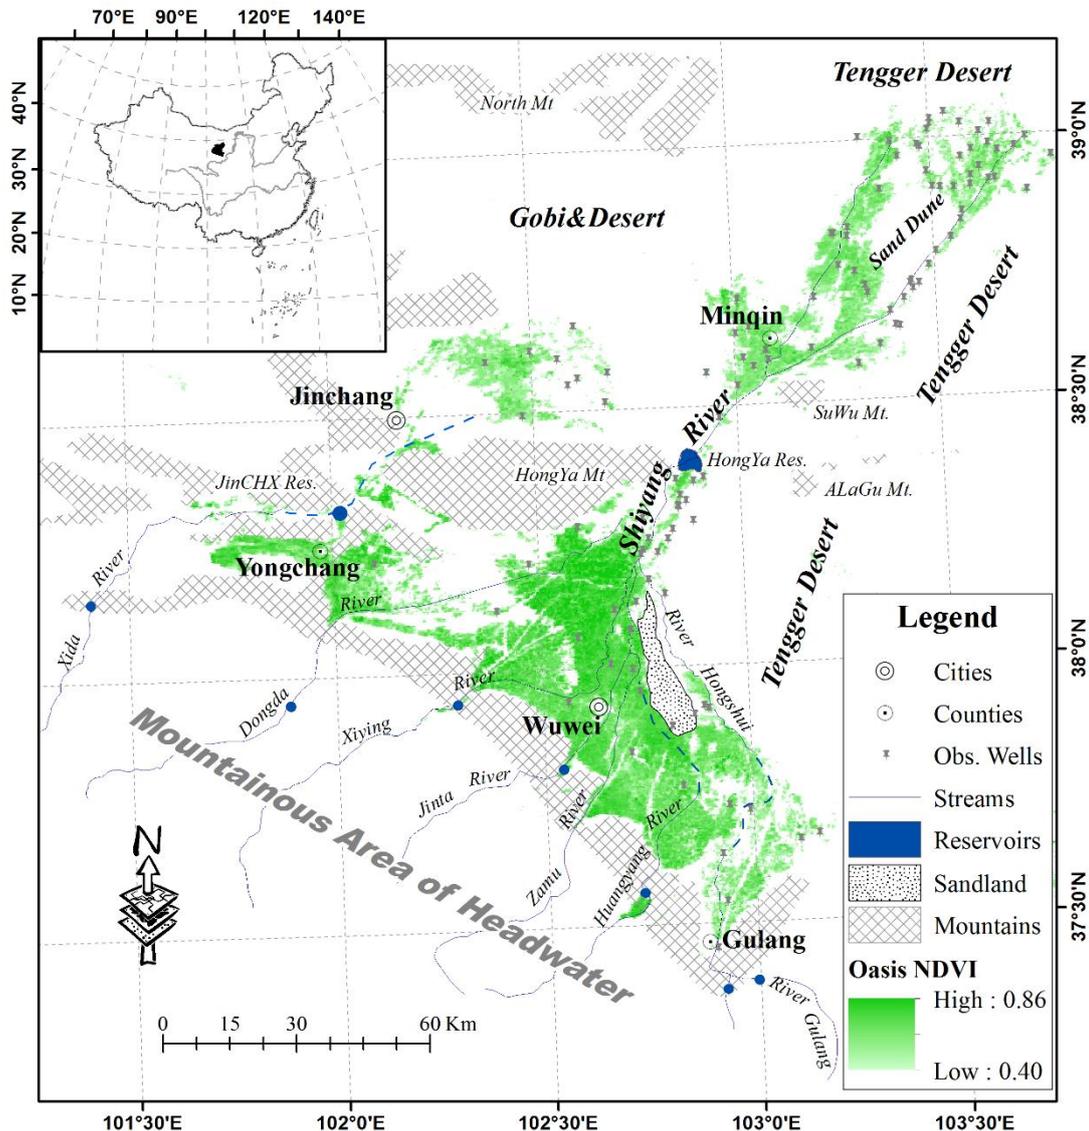

81 anthropogenic modification impacts on complex hydrological processes [31-33]. In  
82 addition, fine-temporal imagery products, such as the NDVI (normalized difference  
83 vegetation index) from Advanced Very High Resolution Radiometer (AVHRR) or  
84 Moderate Resolution Imaging Spectroradiometer (MODIS) sensors have provided  
85 potential long-term land cover change interpretations [34-36], which is also an  
86 important widely used indicator for studying the carbon-water balance in the context of  
87 climate change and plays a key role in water management [37-41].

88       Given the high-level complexity of multifactor interactions in natural-artificial  
89 water systems [42], the hydrological responses to climate and human impacts across a  
90 whole basin are difficult to quantifiably predict. In particular, the quantification of the  
91 relationship between the groundwater system and oasis scale [43] in arid inland river  
92 basins has rarely been reported. In this study, a 30-year data package was prepared,  
93 which includes hydrometeorology, remotely sensed NDVI, GLEAM-AET and other  
94 data. The objective of the study was to analyze oasis changes during the 1981 to 2010  
95 period, determine oasis vegetation water consumption using GLEAM-AET data  
96 combined with surveys of water utilization in life and industrial systems, calculate oasis  
97 water consumption and water deficit, and then assess groundwater abstraction and its  
98 effectiveness in the regional groundwater system. The study could help residents better  
99 understand the artificial impacts on arid hydrological processes and benefit water  
100 planning and watershed management in arid regions under the background of climate  
101 change.

102 **Method**

103 **Study area**

104 The Shiyang River Basin (SYRB) is located in the easternmost part of the Hexi  
105 Corridor, which is mainly formed by 7 upstream rivers sourced from Qilian Mountain  
106 (southwestern area shown in Fig. 1). The Shiyang River flows north and passes Hongya  
107 Mountain, flowing into the Minqin district in the lower reaches. The flow generation  
108 area is located in the alpine zones with elevations ranging from 5130 m to 1855 m, and  
109 this area is dominated by lower Paleozoic epimetamorphic rocks and intensively cutting  
110 river networks. Groundwater is mainly fissure vein and interlayer water, which  
111 discharges into the river channels, flowing out of the mountainous outlets and into the  
112 middle and lower reaches where the elevation ranges between 1855 m to 1260 m, from  
113 the northernmost part of the southern mountains to the edge of the northern desert.  
114 Channel river water infiltrates and percolates into the deep Quaternary alluvial fans and  
115 deep underground from 100 m to more than 200 m in the south slope area of the  
116 mountains, overflowing at the edge of the fans as springs and accumulating again in the  
117 land surface rivers; finally, this water cuts through the northern mountain valleys and  
118 partially becomes groundwater in the lacustrine deposit system. The remaining water  
119 forms ephemeral rump lakes and is eventually consumed by evapotranspiration,  
120 maintaining the regional water balance in the area [44]. Land covers show significant  
121 spatial heterogeneity, with distinct vertical zonation across the basin. The hydrological  
122 conditions in the area are representative of inland river basins [45].

123  
 124 Fig. 1. Location map and oasis distribution in the SYRB. The basin is divided into upper, middle  
 125 and lower reach areas according to regional hydrogeomorphology. The oases are mainly located  
 126 in the latter two reach areas, which north of the Hongya Reservoir are considered to be in the  
 127 lower reaches (administratively part of the Minqin district), and others are considered to be in  
 128 the middle reaches (administratively part of the Wuwei, Jinchang and Yongchang districts).

129 At present, there are nearly 2.4 million people in the SYRB, and the population  
 130 density is over 600 people per km<sup>2</sup> in the oasis area. The amount of water required to  
 131 match socioeconomic development in the area has dramatically increased since the  
 132 early 1980s in conjunction with the extension of arable land. The irrigated area in the  
 133 1970s was approximately 0.25 million ha, which expanded to over 0.4 million ha from  
 134 the 1980s to 2010s. The large demand for agricultural irrigation has increased the use

135 of mountainous discharge and groundwater abstraction. The overexploitation of water  
136 resources has strained the regional developmental capacity for a relatively long time  
137 [46], resulting in a series of hydrological consequences, including considerable  
138 drawdown of groundwater [47]. Land surface ecology has deteriorated due to the  
139 groundwater system decline; most xerophytic shrubs, such as *elaegnus angustifolia*  
140 and white spines, have died out. As desertification increased, native farmers were  
141 forced to migrate out of the area as “environmental refugees” [16].

#### 142 **Data collection and processing**

143 Hydrometeorological data were collected in or near the SYRB, including data from  
144 10 national weather stations (China meteorological data sharing network,  
145 <http://cdc.cma.gov.cn>) and seven hydrological observational stations (Gansu Province  
146 Bureau of Hydrology and Water Resources Monitoring) at the outlets of the  
147 mountainous sub-basins. The double-mass curve method [48] was used to check  
148 consistency for each hydrometeorological factor. The analogy method (linear) was  
149 adopted to interpolate or extend the missing data to complete the full 30-year series  
150 from 1981 to 2010. Actual evapotranspiration (AET) data were sourced from GLEAM  
151 (Global Land Evaporation Amsterdam Model, <http://www.gleam.eu>) datasets with a  
152 spatial resolution of  $0.25^\circ$ , which have been verified to agree well with land surface  
153 flux observations in China [49-51]. Especially in arid northwestern China, which has  
154 few observation stations, GLEAM-AET can help to obtain spatially and temporally  
155 better regional AET [52-53]. Compared with other AET products (e.g., MOD16, JRA,  
156 GLDAS), GLEAM-AET has higher spatial and temporal resolutions ( $0.25^\circ$ , 1 d) and

157 matches better with data requirements in basin-scale studies. The spatial distribution of  
158 different AET products was similar to some extent, although the expression of high  
159 values of MOD16 AET was too large [54], and the seasonal volatility of GLDAS AET  
160 was relatively high, especially in spring [55]. Monthly GLEAM-AET data collected  
161 over a year was accumulated into the annual GLEAM-AET from 1981 to 2010. All  
162 AET data are resampled to a 250 m resolution to maintain consistency with other data.  
163 We collected well-monitored groundwater data from administrative units, including the  
164 Gansu Province Bureau of Hydrology and Water Resources Monitoring, Gansu  
165 Province Geology Survey, and Gansu Province Environmental Protection Agency. Data  
166 from the 129 monitoring wells were mainly distributed in the oasis area. Data for the  
167 local socioeconomy and the related water utilization were sourced from official  
168 statistics. The NDVI data required for the study were derived from the AVHRR, 8 km  
169 resolution, 1981 to 2006, (<https://ecocast.arc.nasa.gov/>) and the MODIS, 250 m  
170 resolution, 2001 to 2010, (<http://glovis.usgs.gov/>). The land use/cover map used as the  
171 basis for calibration and validation of land cover classification was obtained from  
172 China's National Land Cover Dataset (NLCD 2000, <http://www.resdc.cn/>).

### 173 **NDVI data cross-calibration**

174 The AVHRR and MODIS NDVI products were used for determination of the  
175 maximum pixel NDVI value by the maximum-value composite (MVC) method in this  
176 study. All of the remotely sensed data were resampled into 250 m×250 m images to  
177 keep the spatial resolution identical. Next, series consistency was assessed and cross-  
178 calibrated by correlating corresponding pixels during the overlapping time period from

179 2001 to 2006 [34]. A linear regression method implemented for the overlapping time  
180 period was used to assimilate the two series for the extension of data to the full time  
181 series from 1981 to 2010. The regressive equation for cross-calibration was found in  
182 the following linear form:

$$183 \quad \text{NDVI}_{\text{MODIS}} = 0.87\text{NDVI}_{\text{AVHRR}} + 0.21 \quad (5)$$

184 The consistency of the two NDVI series was verified, with a correlation coefficient  
185 of 0.79 ( $P \leq 0.05$ ). The assimilated NDVI dataset could be considered satisfactory for  
186 series extension, and the data resolution was treated at the same level as the MODIS  
187 data.

#### 188 **Variation statistics**

189 The spatiotemporal variations in the key factors are analyzed using zonal statistics  
190 and Sen's slope method [56]. Sen's slope is a widely used method for variation analyses  
191 of hydrological and meteorological series. Judgment is based on the median of the  
192 series of slopes. When evaluating the variation trend and amplitude of the time series,  
193 the Sen's slope method can reduce or avoid the impact of data anomalies and omissions.

194 The formula is outlined as follows:

$$195 \quad \text{Sen}_{ij} = \text{MEDIAN} \frac{(X_j - X_i)}{(j - i)} \quad (1)$$

196 where  $\text{Sen}_{ij}$  is Sen's slope; and  $X_i$  and  $X_j$  represent the sequential values  
197 corresponding to times  $i$  and  $j$ , respectively, where  $1 < i < j < n$ ,  $n$  is the length of the  
198 series.

#### 199 **Determination of oasis extent**

200 The area of the oasis was determined by coupling thresholds from the remotely  
201 sensed NDVI value and DTM datasets. Thresholds of vegetation greenness (NDVI

202 value), altitude (DEM) and slope (derived from DEM) were defined according to the  
203 AOI (Area of Interest) training samples corresponding to the land cover types illustrated  
204 in an NLCD map. The above thresholds were used to determine the yearly extent of the  
205 oasis in the plain area of the SYRB.

206 Analysis of the AOIs resulted in thresholds of altitude  $\leq 2200$  m and slope  $\leq 7^\circ$ ,  
207 corresponding to locations of arable oases that were mainly distributed in plain areas,  
208 reflecting that significant cultivation occurred in the relatively flat area with lower  
209 altitude in the SYRB. The annual maximum NDVI value based on the MVC method  
210 was trained into  $\geq 0.4$  in these areas, including small areas of forest and grassland with  
211 high land coverage supported by irrigation, near water bodies or in areas with shallow  
212 groundwater burial. Other land cover types, such as sparse vegetation (arid or semiarid  
213 shrubs or grassland) and bare land (desert or Gobi), were excluded because the focus  
214 of this study is mainly on artificial water utilization and its effectiveness in groundwater  
215 systems.

#### 216 **Regressive module of AET**

217 The driving mechanism of oasis AET was explored based on regressions by setting  
218 areal averages of air temperature (T), precipitation (P) and the NDVI values as  
219 independent variables under a multi-linear module at the monthly time scale. For  
220 reasonable regression fittings, AIC (Akaike information criterion) values [57] were  
221 calculated step by step under different parameter settings to assess the reliability of the  
222 model's capacity and parameter selection. The data used to interpret the influencing  
223 mechanism of the AET dynamics is the GLEAM-AET product, which is considered to

224 be the observed AET series. During the process of the stepwise regression, we used the  
225 whole time series (1981-2010) for exploration of the driven module:

$$226 \quad \text{AET} = (\sum b_i * C_i) + \varepsilon \quad (2)$$

227 where  $b_i$  is the regression coefficient for the key climatic or vegetative index ( $C_i$ )  
228 and  $\varepsilon$  is a constant term.

### 229 **Groundwater dynamics**

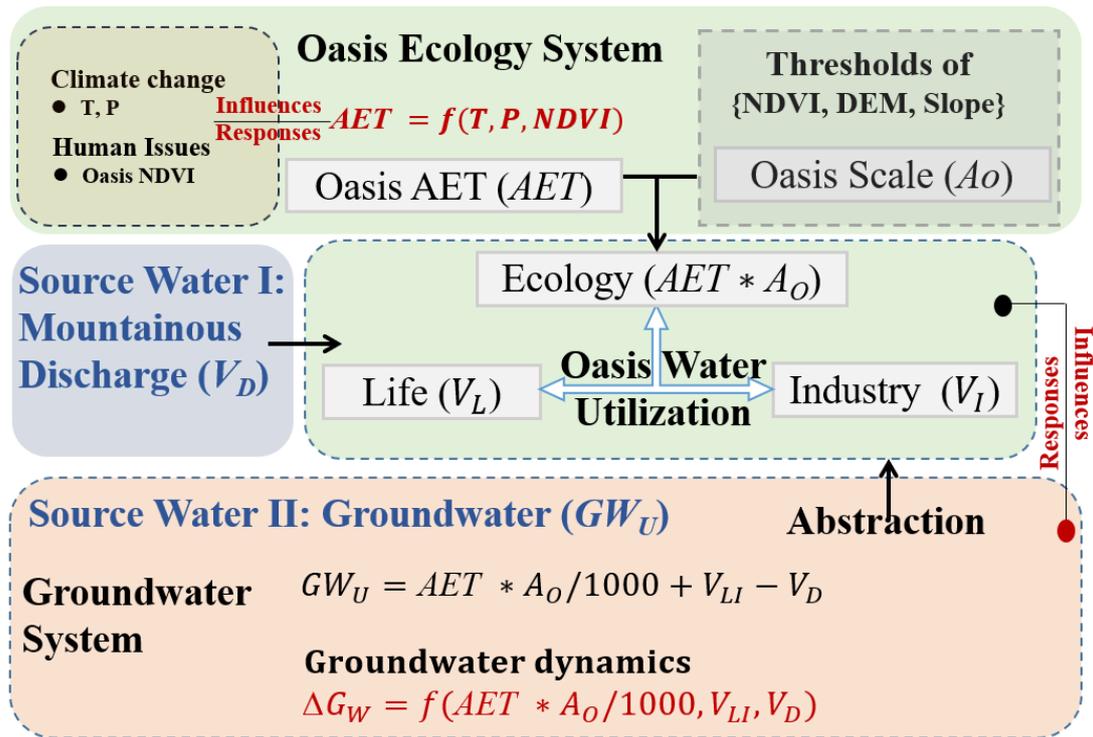

230 Flooding irrigation in the study area dominated infiltration and percolation through  
231 the soil layer to the phreatic system. We assume that the recharged groundwater part  
232 would finally provide abstraction and contribute to AET consumption in the oasis area.  
233 Thus, groundwater utilization could be generally illustrated by a simple water balance  
234 module under a “net” framework (Eq. 3). Precipitation is excluded because it is rarely  
235 able to recharge groundwater systems in arid regions where precipitation is within 100-  
236 200 mm/a [47, 58-59]:

$$237 \quad \text{GW}_U = \text{AET} * A_O / 1000 + V_{LI} - V_D \quad (3)$$

238 where  $\text{GW}_U$  is the annually positive/negative balance of the groundwater ( $10^8 \text{ m}^3$ );  $A_O$   
239 is the area of the oasis (104 ha);  $V_{LI}$  is the surveyed water consumption for life and  
240 industrial purposes ( $10^8 \text{ m}^3$ ); and  $V_D$  is the division of mountainous discharge that  
241 supports oasis water utilization ( $10^8 \text{ m}^3$ , which could be determined by surveying water  
242 division works at the mountain outlets and the Hongya Reservoir, which provides water  
243 to the lower area of the basin). Number 1000 is the arithmetic operator.

244 We consider the groundwater dynamics to be a holistic consequence influenced by  
245 land surface and underground water supply and utilization. Thus, considering the  
246 observations of mountainous discharges, surveyed life and industrial water utilization

247 and the simulated/monitored AET and  $A_O$ , the relationships between groundwater level  
 248 dynamics and other factors could be further explored using the following regressive  
 249 formation:  
 250 
$$\Delta G_W = f(AET * A_O/1000, V_{LI}, V_D) \quad (4)$$
  
 251 where  $\Delta G_W$  is the accumulative dynamics of the groundwater level according to the  
 252 regional average of well monitoring.

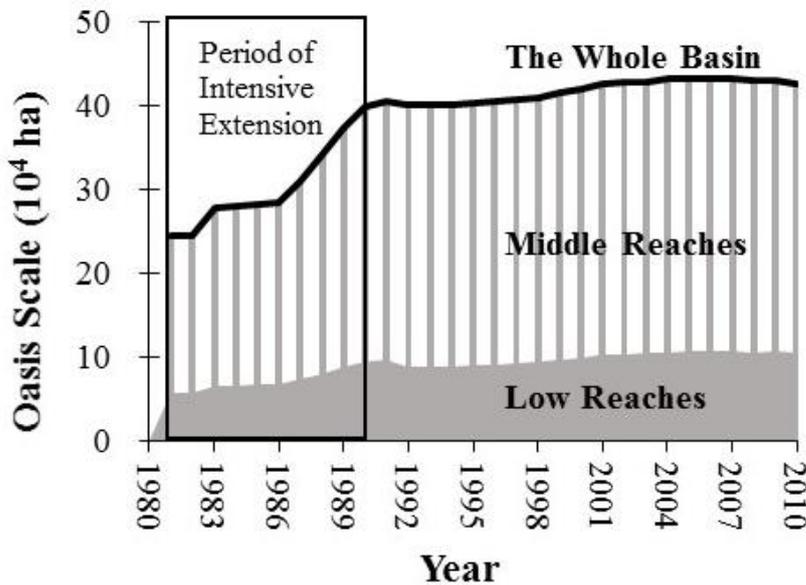

253  
 254 Fig. 2. The coupling framework determining the groundwater dynamics in response to oasis  
 255 water consumption through regional AET.

256 **Results**

257 **Oasis scale from 1981 to 2010**

258 The scale of the oasis continued to increase during the period. Surveys and our  
 259 analysis both pointed to a significant extension of the irrigated oasis scale during the  
 260 1980s (Fig. 3). The oasis area increased from  $24.5 \times 10^4$  ha to nearly  $40 \times 10^4$  ha over the  
 261 ten-year period. Subsequently, the increase in oasis area became slighter than previously.

262 In the late 2000s, a small shrinkage was found in the middle reaches, which occupied  
 263 approximately 77% of the total oasis area of the basin.

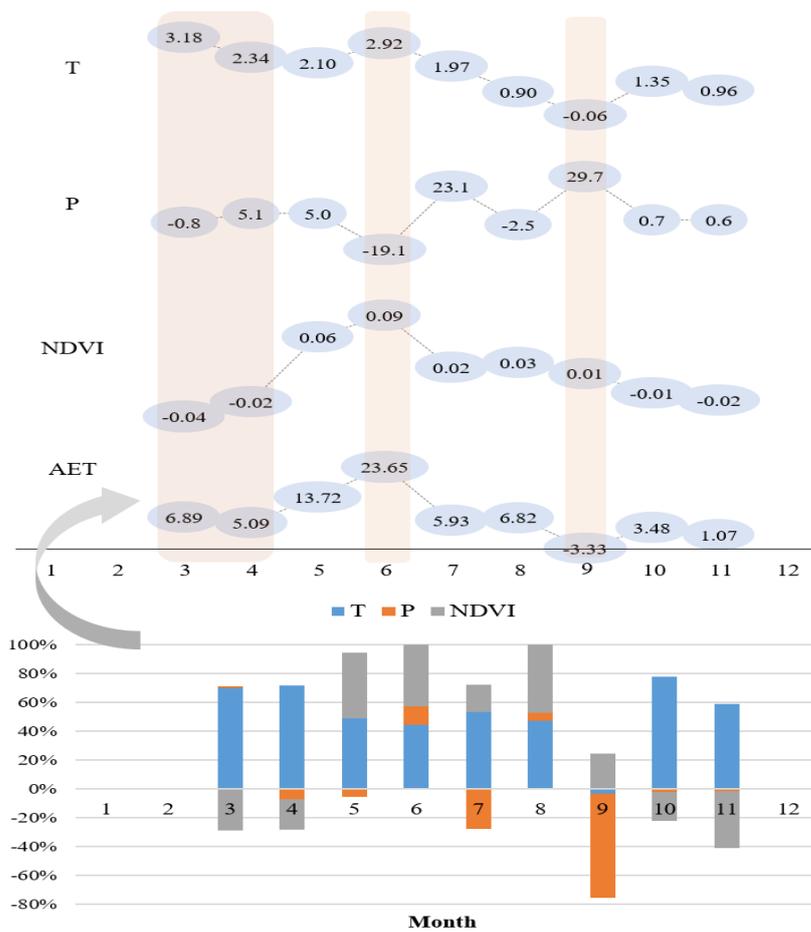

264  
 265 Fig. 3. Changes in the oasis scale in the SYRB from 1981 to 2010.

266 **Correlation between AET and climatic and vegetative factors**

267 *Changes in the key variables*

268 Statistics of the monthly variation in the 30-year span resulted in different  
 269 changeable amplitudes for all 4 variables (Fig. 4). Generally, warming facilitated aridity  
 270 in arid areas because of sparse precipitation, although artificial irrigation changed the  
 271 water supply and supported vegetation growth. Greenness reflected by NDVI presented  
 272 suppression in most of the initial growing stages, regardless of whether the precipitation  
 273 increased or decreased. The AET increased along with the upward air temperature in  
 274 each stage (Fig. 4, columns 3-4), reflecting the facilitation of warming on the regional  
 275 AET. Most crops in the study area turned into developing/middle stages from May to  
 276 July. Statistics showed in an obvious decrease in precipitation but a remarkable increase  
 277 in AET in June (Fig. 4, column 6). Given the small amount of rainfall, irrigation played  
 278 an important role in this stage. Additionally, less precipitation may correspond to more

279 sunny days, verifying the increasing AET requirement at this stage. Similarly, increased  
 280 rainfall (more cloudy days), combined with the decrease in air temperature in  
 281 September, suppressed AET to some extent, although the greenness (NDVI)  
 282 strengthened (Fig. 4, column 9). This indicates that except for vegetative transpiration,  
 283 environmental loss through soil evaporation was necessary to support the total AET  
 284 water consumption.

285  
 286 Fig. 4. Monthly variations in each factor and their contributions to AET variation. The positive  
 287 and negative signs represent the enhanced or weakened effects.

288 ***Regressive module of AET***

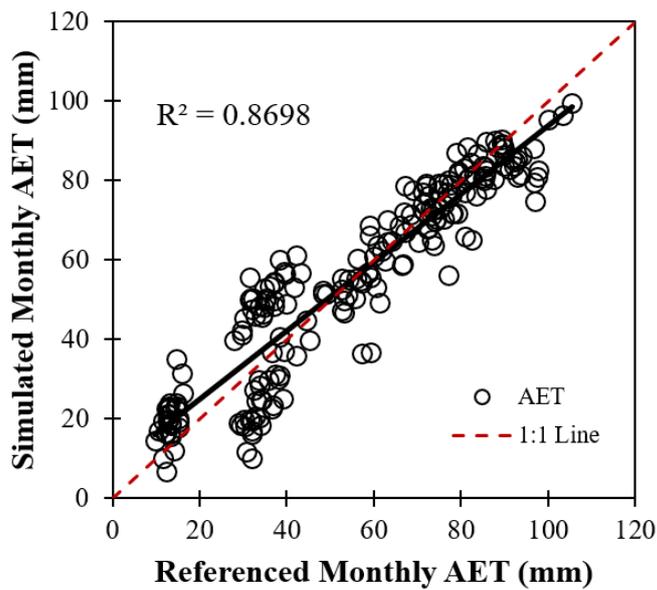

289 For a better understanding of AET variation under the background of climate  
 290 change and human activities in the oasis area, the growing season GLEAM-AET  
 291 (mainly during the time period from March to November in the area) was regressed in

292 a stepwise manner using the key factors of T, P and NDVI, as illustrated in Eq. (2).  
293 Zonal statistics were used to calculate values of the four factors at a monthly time scale.  
294 We used the forward stepwise regression method to input factors and compared the AIC  
295 values. The AICs decreased to 994.93, 970.48, and 954.79 as the number of parameters  
296 increased from 1 to 3, respectively, indicating that the effectiveness of the selected  
297 model and variables in AET simulation is reliable. Regressions showed positive  
298 influences of T and NDVI but a negative influence of P on regional AET variations.  
299 The final module by stepwise regression was calibrated as follows:

$$300 \quad \text{AET} = 3.59 \times T - 0.16 \times P + 117.23 \times \text{NDVI} - 24.95 \quad (6)$$

301 where AET represents the simulated AET in the oasis area when key climatic factors  
302 and the vegetative index are considered to be auxiliary variables, T is the average  
303 monthly air temperature (°C), P is the monthly total precipitation (mm), and NDVI is  
304 the MVC-based monthly NDVI.

305 The stepwise regression was fitted with satisfactory precision, and the correlation  
306 coefficient was 0.87 when compared with the GLEAM-AET. (Fig. 5), meaning that the  
307 regressive module could explain approximately 87% of the GLEAM-AET.

308

309 Fig. 5. Module validation of the climate and vegetation factors driving regional AET.

310 ***Relationship between AET and the influential factors***

311 Module applications and statistics revealed that during the 1981 to 2010 period, the  
 312 air temperature increased by 1.74°C, facilitating an increase in AET by 56.2 mm  
 313 (approximately 32.3 mm/°C). The increase in precipitation during the growing season  
 314 over the 30-year period was summed to 41.7 mm, with an approximately 6.7 mm  
 315 suppression of AET (an approximate ratio of -1.6 mm/10 mm). The oasis scale  
 316 presented extension according to remote sensing monitoring, and the NDVI value  
 317 averaged into a total increase of 0.12, resulting in an AET of an additional 13.7 mm (an  
 318 approximate ratio of 11.4 mm corresponding to the strengthened unit greenness of 0.1).  
 319 The above aggregated findings pointed to unit influences of 32.3 mm/°C, -1.6 mm/10  
 320 mm and 11.4 mm/0.1 in the changeable T, P and NDVI, respectively, on oasis AET  
 321 variations in the SYRB (Fig. 9b). Consequently, the contribution ratios of climate  
 322 change (varied T and P) and oasis ecology (mainly supported by irrigation) to the  
 323 changed AET were calculated to be 78% and 22%, respectively, at the 30-year time

324 scale. Although artificial irrigation basically supported the oasis ecology, it was  
325 warming that dominated the increase in the consumptive oasis AET in arid regions, as  
326 in the SYRB, given a growing vegetation condition of adequate water supply.

### 327 **Net water consumption in the oasis area of the SYRB**

328 Net oasis water consumption was determined by the product of GLEAM-AET and  
329 the remote sensing-based delineation of the oasis scale. Spatial statistics resulted in  
330 average AET consumptions of 359.97 mm/a and 442.46 mm/a, corresponding to total  
331 oasis water utilizations of  $11.04 \times 10^8 \text{ m}^3$  and  $3.89 \times 10^8 \text{ m}^3$  in the middle and lower  
332 reaches, respectively. Combined with household and industry water consumption,  
333 averaged as  $1.96 \times 10^8 \text{ m}^3$  and  $0.17 \times 10^8 \text{ m}^3$  in the middle and lower oases during the  
334 reference period, respectively, the net water consumption in the oasis area of the SYRB  
335 was  $17.06 \times 10^8 \text{ m}^3$ , although multi-yearly monitored mountainous discharges were  
336 averaged as a total volume of  $13.99 \times 10^8 \text{ m}^3$  over the 30-year period. When considering  
337 possible water loss through evaporation in rivers, wetlands and reservoirs, the total  
338 water demand far exceeded the available water resources in the SYRB.

### 339 **Responses of the groundwater system to oasis water utilization**

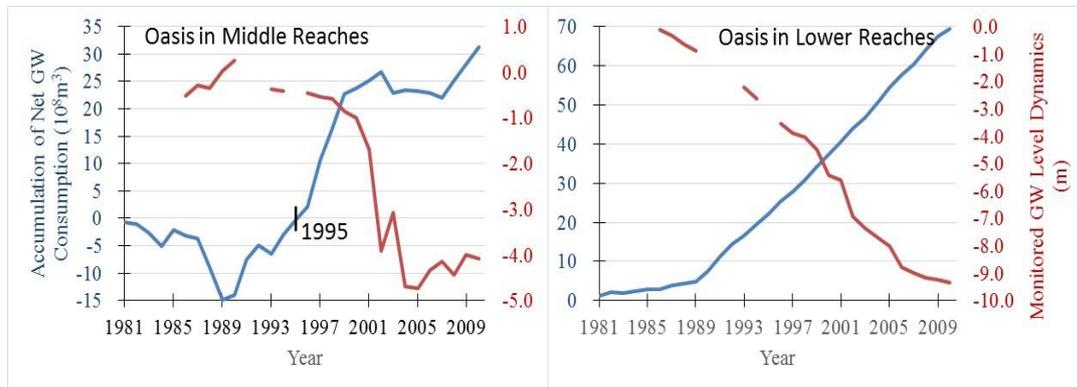

#### 340 *Net consumption of groundwater*

341 Due to the large water requirement in the oasis area, water utilization has  
342 continuously increased in China's inland river basins in recent decades. At the basin  
343 level, the gross supply of water resources consists of two parts: the water amounts  
344 extracted from mountainous discharges and groundwater abstractions. According to our  
345 statistics, the reservoir-canal systems extracted almost all mountainous discharges for  
346 oasis water utilization in the middle and lower reaches, which provided approximately

347 82% of the total oasis water consumption; the remainder was mainly supported by local  
348 groundwater abstraction.

349 A series of simulated oasis AET and remote sensing monitored oasis scale data,  
350 combined with monitored or surveyed mountainous discharges and life and industrial  
351 water use, were input as parameters into Eq. (3) to determine the net balance of the  
352 groundwater system ( $GW_U$ ). Groundwater levels from monitoring wells (Fig. 1) were  
353 treated as differential series to illustrate the dynamics, which were spatially averaged  
354 to represent the regional responses corresponding to net groundwater consumption.  
355 Collaborative trends of the two accumulative series in both the middle and lower  
356 reaches (Fig. 6) indicated that quantification under a net balance module was reliable  
357 for estimating the influences of oasis water utilization on the groundwater system.  
358 Obvious differences in groundwater utilization and responses were found in the middle  
359 and lower reaches. More net consumption of groundwater led to near-linear and greater  
360 drawdown of the groundwater level in the lower reaches, while that in the middle oasis  
361 area fluctuated occasionally as a result of the large percolation recharge from channel  
362 transfer and irrigation. Consequently, before 1995, there was an overall positive  
363 groundwater balance in the middle part of the basin, and the total water consumption in  
364 the area was less than the mountainous discharge provided. Conversely, there was  
365 continual drawdown in the lower oasis area over the whole period, indicating a  
366 continuously negative balance in the groundwater system there. Considering water  
367 sources, the relatively smaller drawdown of the groundwater level in the area of the  
368 middle reaches benefitted from the advantages of the mountainous discharge, while the

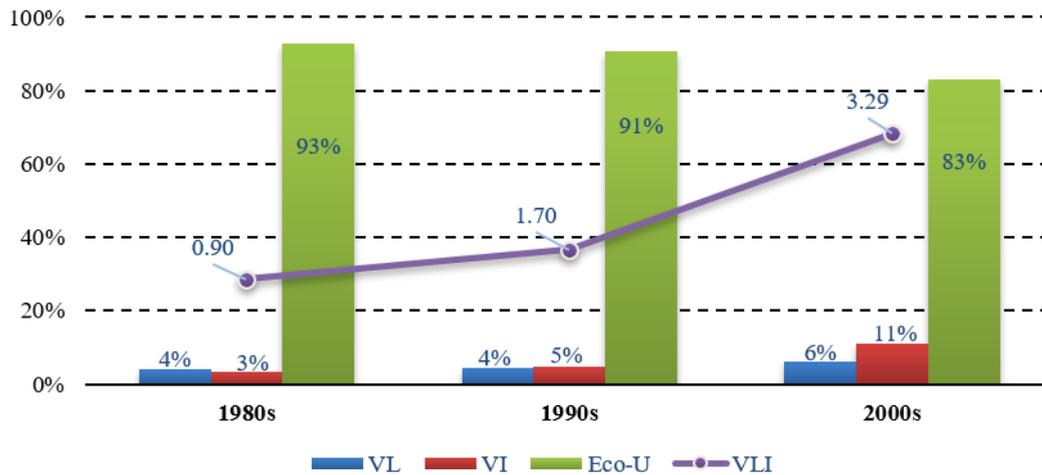

369 obviously severe decline in the underground water system in the lower reaches was  
 370 mainly because of the finite water division into the Hongya Reservoir and the intensive  
 371 abstraction.

372  
 373 Fig. 6. Accumulation trends of net groundwater consumption and groundwater level dynamics.  
 374 Inverse trends were found for both of these factors in oasis areas in the middle and lower reaches  
 375 of the SYRB.

376 ***Relationship between groundwater dynamics and influential factors***

377 Accumulative series of the variables in Eq. (4) were stepwise regressed to calibrate  
 378 the key factors affecting the groundwater dynamics. Life and industrial water ( $V_{LI}$ ) was  
 379 considered to be one of the potential factors influencing groundwater dynamics in the  
 380 equation. This value increased from  $0.9 \times 10^8$  to  $3.29 \times 10^8$  from 1981 to 2010, although  
 381 the proportions were still small (only 7%-17% to the annual total, Fig. 7).  $V_{LI}$  was  
 382 excluded during the regressive exploration for the relatively small fitting contributions,  
 383 meaning that the groundwater dynamics were not synergetic or significant to the  
 384 increase in life and industrial water use, and key factors influencing regional  
 385 groundwater dynamics were mountainous discharge and oasis ecological water  
 386 utilization.

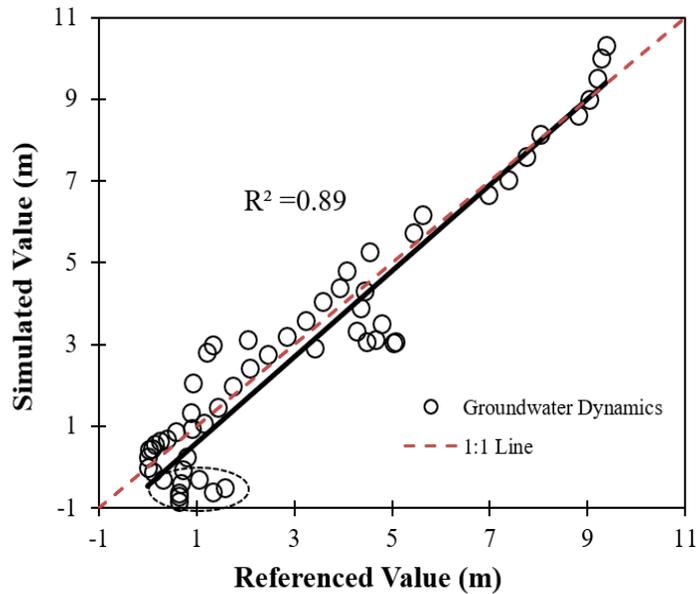

387

388 Fig. 7. Percentages of water used for different purposes in the SYRB. (Legend: VL, VI and Eco-  
 389 U represent water use by life, the manufacturing industry and oasis consumption, respectively.  
 390 V<sub>LI</sub> shows the variation in life and industrial water use during different decades (in  $10^8 \text{ m}^3$ .)

391 Stepwise regression resulted in the following expression:

$$392 \quad \Delta G_W = 0.138AET * A_O/1000 - 0.111V_D + 0.06 \quad (7)$$

393 The regression revealed that the main factors influencing groundwater variation  
 394 were oasis AET, oasis scale and water diversion by different kinds of water conservancy  
 395 projects. The regression coefficient was calibrated to an  $R^2$  of 0.89 (Fig. 8), indicating  
 396 that the relationship between the four variables (dependent variable was the monitored  
 397 groundwater dynamics) was essential. A negative value indicates an increase in the  
 398 groundwater level, generally corresponding to slight dynamics (points in the ellipse).  
 399 Eq. (7) is considered to express the relationship among the four variables with  
 400 satisfactory reliability at a regional level.

401

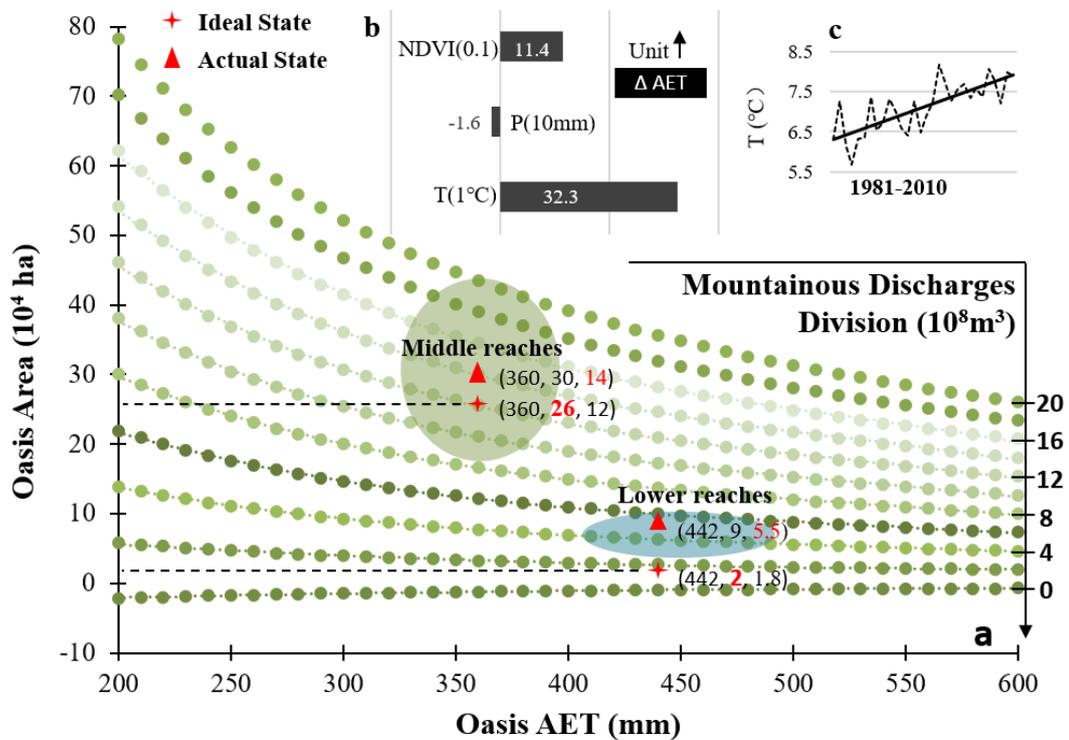

402 Fig. 8. Calibration of the groundwater dynamics driven by oasis AET, scale and mountainous  
 403 discharge.

404 ***Ideal oasis scale for a sustainable groundwater system***

405 Under the framework illustrated in Eq. (7), the combination of irrigation area and  
 406 oasis AET impacted the groundwater level drawdown, while the diversion of land  
 407 surface water could counteract and retard the decline in the groundwater system. Given  
 408 the neglect of local interactions between the land surface and underground water system  
 409 (e.g., temporary exchanges of water in some of the river sections, local depressions due  
 410 to intensive abstractions, evaporation in water bodies) and the induced errors in  
 411 quantifying the relationships, the scenario of no groundwater drawdown could aid in  
 412 further exploring the rational or ideal oasis water utilization under the background of  
 413 human regulation and climate change. Fig. 9 was plotted in correspondence to different  
 414 surface water divisions under the hypothesis of no groundwater level drawdown, which  
 415 could also aid in understanding oasis water utilization when considering groundwater  
 416 system recovery. Ellipses present ranges of oasis AET and scale from 1981 to 2010 in

417 the SYRB. Triangles indicate the average of the variables, while the crosses represent  
418 the ideally rational oasis area supported by the real land surface water diversion without  
419 groundwater drawdown. During the time period from 1981 to 2010, observations and  
420 simulations revealed numerical ranges of oasis AET (334-396, in mm) and oasis scale  
421 (18.4-45.0, in  $10^4$  ha) in the middle reaches, while those in the lower reaches were in  
422 the ranges of 408-483, in mm and 4.5-11.1, in  $10^4$  ha for oasis AET and scale,  
423 respectively (ellipse in Fig. 9a). Oasis AET and scale were averaged into to mm and  $30$   
424  $\times 10^4$  ha in the period in the middle reaches, respectively, pointing to a virtual water  
425 diversion of  $14 \times 10^8$  m<sup>3</sup> if there were no groundwater drawdown. This scenario was  
426 impossible because of policy-regulated water division to the lower reaches. The deficit  
427 was matched by groundwater abstractions. The situation was the same in the lower  
428 reaches, where the 30-year average oasis AET and scale were 442 mm and  $9 \times 10^4$  ha,  
429 respectively, corresponding to a requirement of  $5.5 \times 10^8$  m<sup>3</sup> for land surface water  
430 division. This situation occurred in the 1950s-1960s when the oasis scale in the middle  
431 reaches was relatively small. Real water diversion for oasis utilization in the middle  
432 reaches and lower reaches averaged approximately  $12 \times 10^8$  m<sup>3</sup> and  $1.8 \times 10^8$  m<sup>3</sup>,  
433 respectively, from 1981 to 2010. If the decline in the groundwater system did not  
434 continue, the ideal oasis scale should be approximately  $26 \times 10^4$  ha and  $2 \times 10^4$  ha in the  
435 middle and lower reaches (bold red numbers in Fig. 9a), respectively, meaning that the  
436 ideal shrinkage of the oasis scale for a healthy groundwater system in the SYRB may  
437 be  $11 \times 10^4$  ha. Notably, the above analysis was based on the exclusion of  $V_{LI}$  when  
438 applying the module for discussion. Considering this part of water use would lead to

439 more water consumption and a higher impact on the health of the underground water  
 440 system.

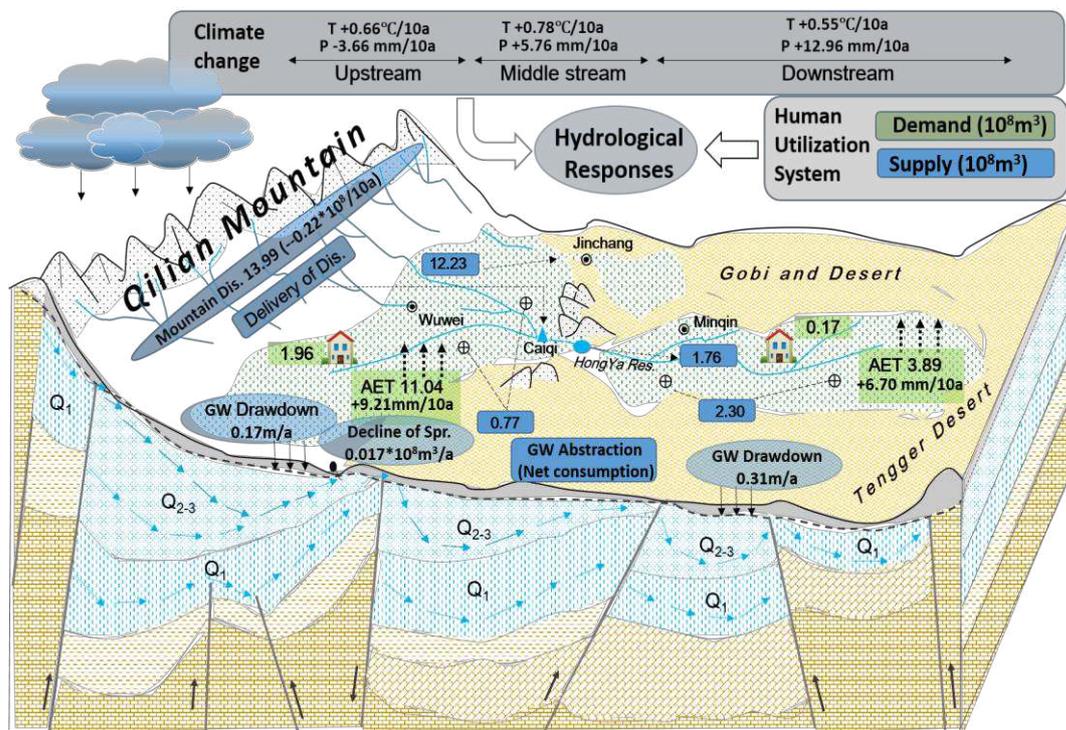

441  
 442 Fig. 9. Ideal oasis water utilization based on consideration of oasis area, AET and mountainous  
 443 discharges (a). Regional AET variations due to unit changes in influential factors (b) and  
 444 increasing air temperature (c) in the SYRB during the 1981 to 2010 period are also presented.

## 445 Discussion

### 446 A 30-year basin water balance in the SYRB

447 In the SYRB, mountainous discharges and abstractions of groundwater supported a  
 448 large oasis AET requirement, combined with industrial water use and household water  
 449 consumption. Sen's slope was used to test T, which presented an overall increase across  
 450 the whole basin, while P decreased in mountains and increased in plain areas during the  
 451 1981 to 2010 period. Under the background of climate change, mountainous discharges  
 452 presented an overall decrease, while the extension of arable land led to an aggregation  
 453 of land surface AET in the irrigated oasis. Reservoir-canal-well systems, initially

454 developed to support the large irrigation demand, led to dried-up river channels in  
 455 addition to regional groundwater drawdown. Statistics in the SYRB revealed that the  
 456 annual rate of groundwater drawdown in the lower area was at a high rate of 0.31 m/a,  
 457 resulting in near-bare spring outflow for a relatively long time. The average drawdown  
 458 rate was 0.17 m/a in the middle reaches. Spring outflow there declined at an annual rate  
 459 of  $0.017 \times 10^8 \text{ m}^3/\text{a}$  during that time period [60].

460  
 461 Fig. 10. Conceptual illustration of groundwater dynamics corresponding to regional climate  
 462 change and oasis water consumption across the SYRB during the 1981 to 2010 period.

463 Mountain discharges from the upper river basins vary over time due to the effects  
 464 of climate change on land surface water flux, while hydrological responses in the  
 465 middle and lower plains are predominantly impacted by human activities. A decrease  
 466 in mountainous discharges, along with an increase in the oasis AET requirement in the  
 467 middle and lower reaches, not only led to depressions of spring outflow and phreatic  
 468 evaporation but also to a reduction in necessary water absorption by roots [61].

469 Degeneration of land cover would lead to a higher risk of oasis destruction due to  
470 interior and circumjacent desertification. In particular, the high risk of oasis survival in  
471 the lower reaches of the SYRB has been verified over the past several decades,  
472 coinciding with desert extension in other areas and with strengthening dust storms in  
473 northwestern China [62]. These impacts indicate the negative results of  
474 overexploitation on water resources and its gradual consequences for regional  
475 hydrology and ecology; additionally, these impacts serve as a warning for pursuing  
476 economic well-being at the expense of the environment. Our study could be considered  
477 a 30-year case example when the above contradictions were remarkable in inland river  
478 systems in arid regions.

#### 479 **Oasis and water management**

480 For the large population (especially farmers) survival, resource shortage-induced  
481 water problems are still crucial to oasis health in the SYRB. Furthermore, an increase  
482 in air temperature, together with strengthened vegetation dynamics, facilitated regional  
483 AET requirements. According to this study, increasing precipitation suppressed oasis  
484 AET, and combined with a reduction in water utilization to some extent, the  
485 effectiveness was slight when compared with the former two factors. Under a  
486 background of warming and facing deterioration of the underground system, rational  
487 development of oasis soil and water needs more attention and better planning. In the  
488 late 2000s, strict rules were implemented to partition water resources between the  
489 middle and lower reaches (division part should not be less than  $2.7 \times 10^8$  m<sup>3</sup> in a year  
490 [63], corresponding to a suitable oasis area of  $4 \times 10^4$  ha according to our study), to cut

491 down groundwater abstraction to maintain a healthy underground system and to  
492 demonstrate advanced water-saving methods in experimental regions (which may lead  
493 to a decrease in the AET requirement). All of these methods have helped but not enough.  
494 On the one hand, we should further improve the crop types in oases by planting more  
495 low water consumption crops and reducing high water consumption crops. On the other  
496 hand, we can reduce cultivated land area, return farmland to forest and grassland,  
497 supervise ground water extraction and even close wells to protect the groundwater  
498 system. In addition, water diversion from outside the SYRB would be the key to  
499 achieving better socioeconomic development under the background of a changing  
500 climate.

## 501 **Conclusion**

502 In this study, various-source data were used to calibrate and determine the driving  
503 factors that influence net oasis water consumption and regional groundwater dynamics  
504 in the selected SYRB of arid northwestern China. Module analyses revealed a warming-  
505 dominated AET increase, while oasis extension led to large amounts of water  
506 consumption and remarkable drawdown of regional groundwater during the 1981 to  
507 2010 period. The drawdown rates of regional groundwater averaged 0.17 m/a and 0.31  
508 m/a in the middle and lower reaches, respectively, indicating an approximately  
509 continuous decline in the basin groundwater system. From the perspective of  
510 groundwater system recovery, our study quantitatively pointed to prominent gaps  
511 between real oasis scales and rational scales in both the middle and lower reaches. For  
512 a sustainable future of population survival and land surface ecology in the SYRB,

513 moderate shrinkage of the oasis scale and water diversion from outside into the basin  
514 would be essential.

# Figures

**Figure 1**

Location map and oasis distribution in the SYRB. The basin is divided into upper, middle and lower reach areas according to regional hydrogeomorphology. The oases are mainly located in the latter two reach areas, which north of the Hongya Reservoir are considered to be in the lower reaches (administratively part of the Minqin district), and others are considered to be in the middle reaches (administratively part of the Wuwei, Jinchang and Yongchang districts). Note: The designations employed and the presentation of the material on this map do not imply the expression of any opinion whatsoever on the part of Research Square concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. This map has been provided by the authors.

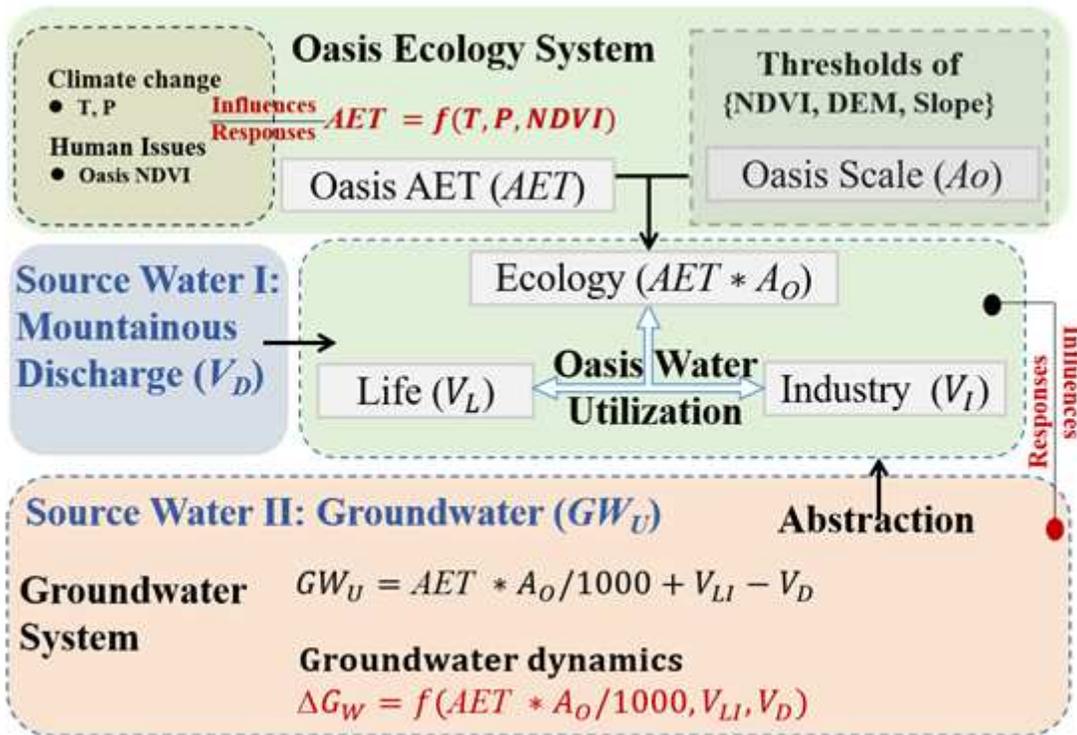

Figure 2

The coupling framework determining the groundwater dynamics in response to oasis water consumption through regional AET.

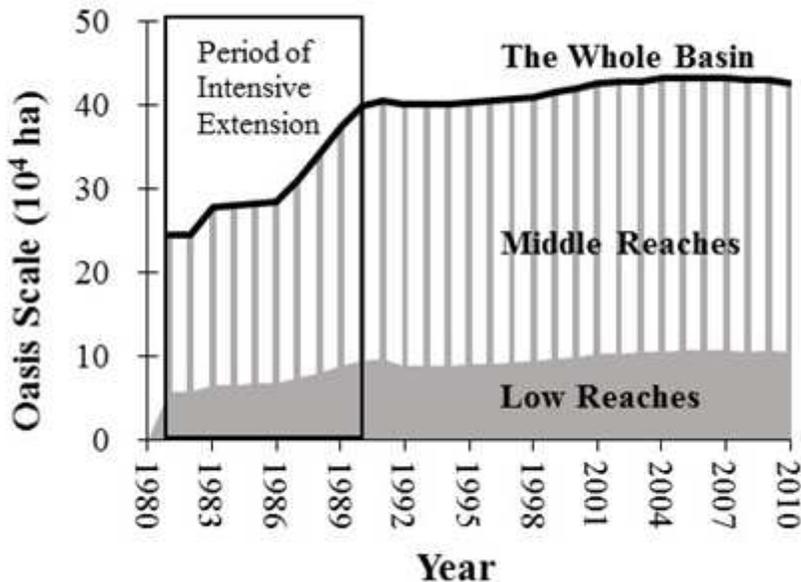

Figure 3

Changes in the oasis scale in the SYRB from 1981 to 2010.

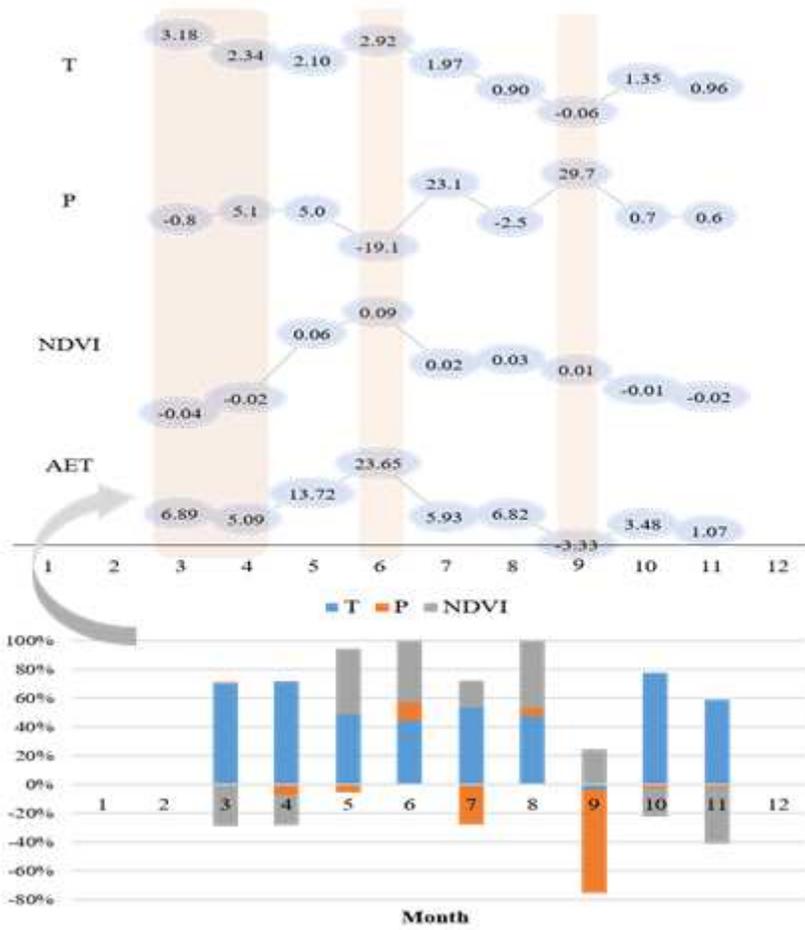

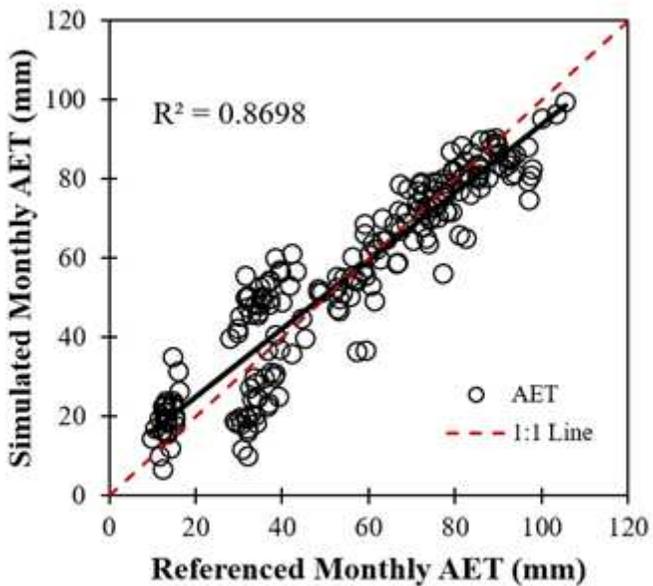

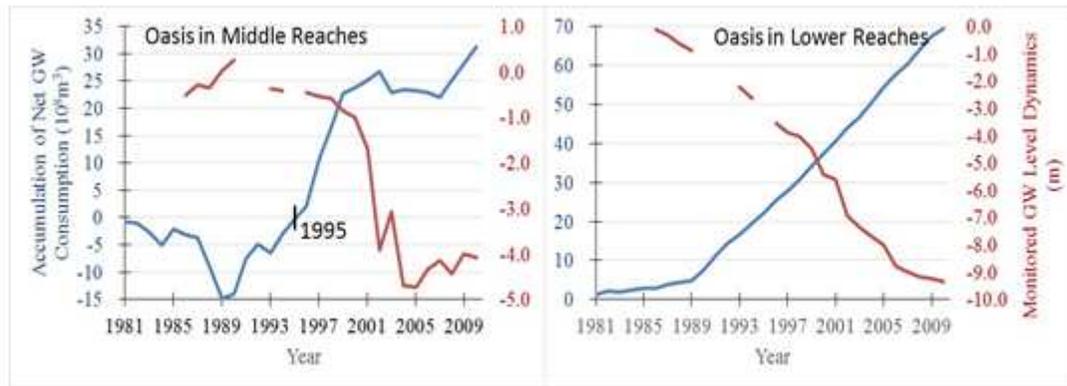

Figure 4

Monthly variations in each factor and their contributions to AET variation. The positive and negative signs represent the enhanced or weakened effects.

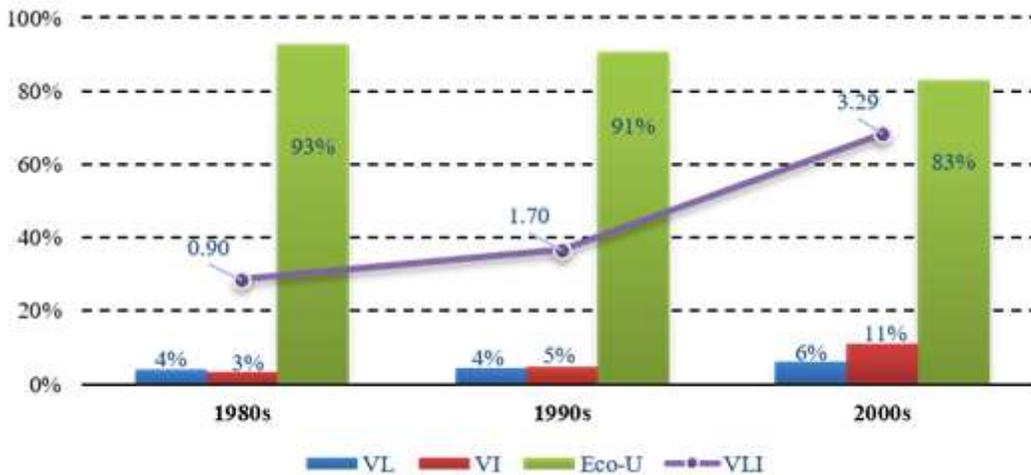

**Figure 5**

Module validation of the climate and vegetation factors driving regional AET.

**Figure 6**

Accumulation trends of net groundwater consumption and groundwater level dynamics. Inverse trends were found for both of these factors in oasis areas in the middle and lower reaches of the SYRB.

**Figure 7**

Percentages of water used for different purposes in the SYRB. (Legend: VL, VI and Eco-U represent water use by life, the manufacturing industry and oasis consumption, respectively. VLI shows the variation in life and industrial water use during different decades (in 108 m<sup>3</sup>).)

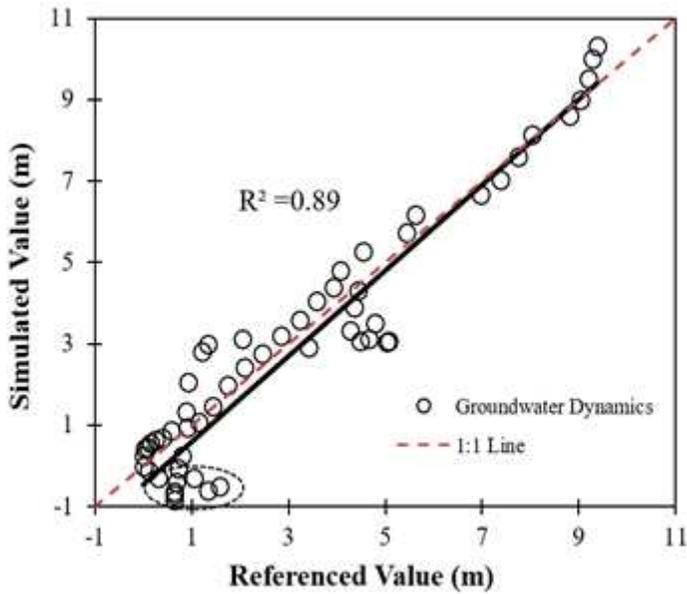

Figure 8

Calibration of the groundwater dynamics driven by oasis AET, scale and mountainous discharge.

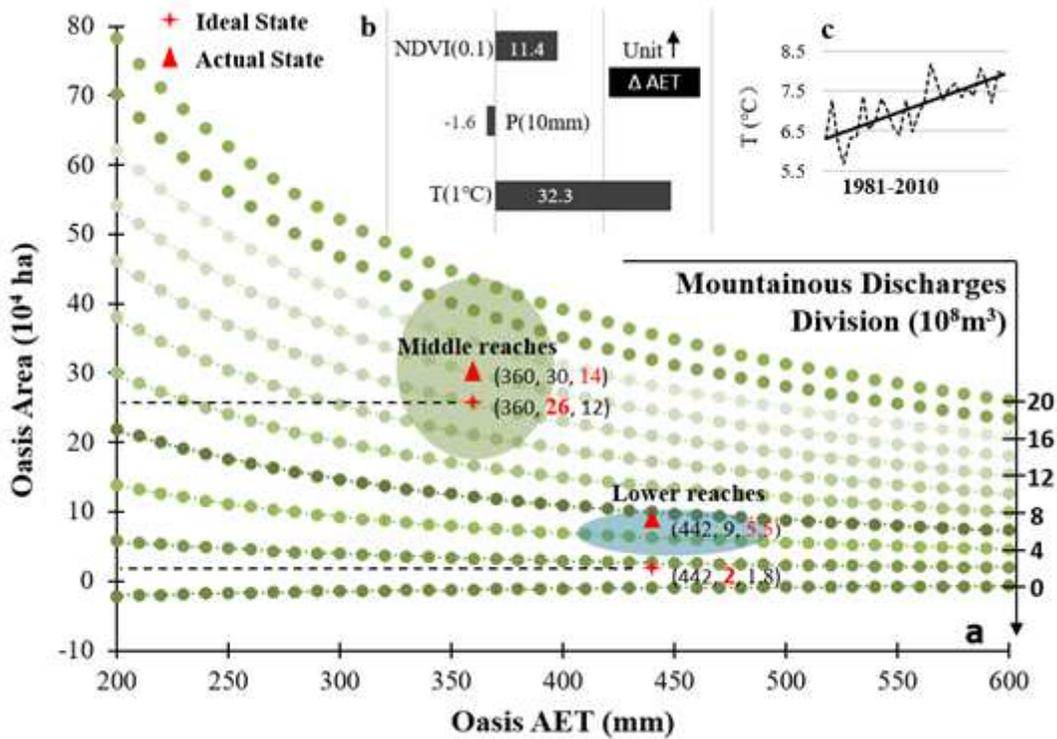

Figure 9

Ideal oasis water utilization based on consideration of oasis area, AET and mountainous discharges (a). Regional AET variations due to unit changes in influential factors (b) and increasing air temperature (c) in the SYRB during the 1981 to 2010 period are also presented.

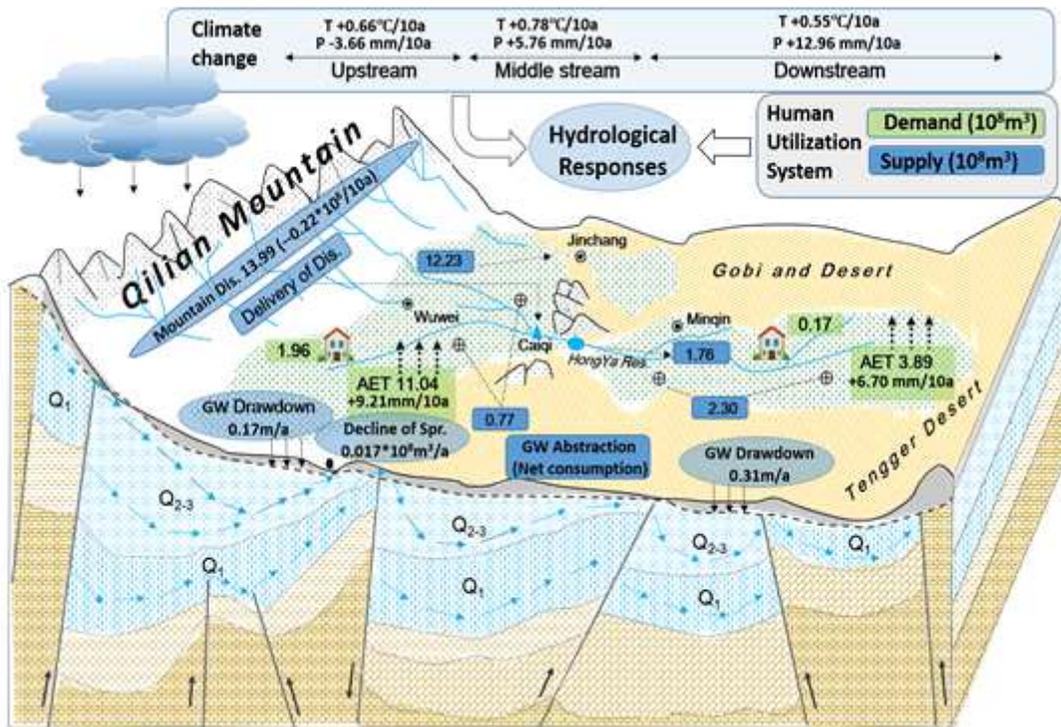

Figure 10

Conceptual illustration of groundwater dynamics corresponding to regional climate change and oasis water consumption across the SYRB during the 1981 to 2010 period.
