Abstract

Objective: Cognitive interventions may be effective in weight loss. The purpose of this study was to assess if cognitive reappraisal (CR; reframing the meaning of a stimulus in order to change the resulting emotional response), can reduce food attentional bias (FAB) using the Visual Dot Probe (VDP) paradigm.

Method: 126 participants (age 27 ± 5.8) were randomly assigned either to a CR or to a control (CN) group. After assessing baseline VDP levels for FAB, participants either wrote sentences that discourage eating fattening food or neutral sentences. Next, all participants performed the VDP post intervention. Participants also self-reported on disturbed eating behaviors and their height and weight were charted. We hypothesized that CR would reduce FAB and that disturbed eating would moderate the association between group and FAB.

Results: FAB decreased post intervention, specifically in the CR group. The bulimia sub-scale showed an interaction between bulimic eating, time and group. Among those who were high on the bulimia scale, the CR group showed lower FAB post-intervention compared to the CN group.

Discussion: This study suggests that CR may decrease the attentional bias toward high-calorie food compared to other strategies in the general population and among people with high bulimia measures, in particular.

Plain English Summary

Obesity has a negative impact on many aspects of life and much research is dedicated to trying to better understand behaviors concerning obesity. People are prone to focus their attention on things that are of importance to them, such as food. When people focus their attention on food, we call this Food Attention Bias (FAB). Cognitive reappraisal (CR) interventions involve the person's conscious cognitive change of the meaning of the situation aiming to consequently change the emotional response to it, such as saying to yourself "I shouldn't eat this because I don't want to get fat". CR has been found to be helpful in lowering FAB using brain imagining techniques but has not yet been studied in cognitive processes. Our study used a Visual dot probe paradigm (VDP) to assess the efficacy of CR on lowering FAB. Two groups, one using CR and a control group were assessed twice on FAB, using the VDP paradigm. Compared to the normal condition, the CR intervention helped reduce FAB. This reduction was especially significant for people with a higher tendency for bulimic behavior. The VDP paradigm, utilizing CR, can be expanded to help build an intervention aimed at reducing FAB over time. This, in turn might bring to weight reduction. People with bulimic tendencies might especially benefit from CR interventions when dealing with weight loss.

Introduction

The shortage of time, and the endless selection of food products can lead people to eat regardless of their hunger and energy needs and consume fast and fat food (Broussard & Van Cauter, 2016; Rey-Lopez

et al., 2014; Siep et al., 2012). Research shows that the appearance of appetizing food products attracts attention and may be enough to trigger a person's food intake for pleasure only, regardless of existential needs (Dietrich, 2017; Siep et al., 2012), which can lead to obesity.

Obesity and disturbed eating

While the global average of obese people stands at 10.7% of men and 15.2% of women over the age of 18, in Israel the picture is even more bleak. Over 23% of men and 27% of women in Israel (age 18 and up) are considered overweight (World Health Organization, 2015). Obesity increases the risk of diseases such as diabetes, various types of cancer and heart disease and is now considered a global epidemic (Nabavi et al., 2015; Rey-Lopez et al., 2014). This study examines a possible way of coping with Food Attention Bias (FAB) that, together with other factors, may lead to obesity. The study examines the impact of a cognitive strategy based on a stimulus re-evaluation technique, on people's susceptibility to FAB to tempting food stimuli, aiming to promote the development of a tool for coping with obesity.

Obesity is defined as a condition of abnormal or excessive fat accumulation in adipose tissue, to the extent that health is impaired (Ogden et al., 2007). The most widely used tool for measuring and diagnosing obesity is the body mass index (BMI) due to its simplicity and low cost (Mei et al., 2002). A value of 30 or higher is considered obese, 25-29.9 is overweight and values that are in between 18.5-24.9 indicate normal weight (Mei et al., 2002; Ogden et al., 2007).

Many factors contribute to the ever-growing epidemic of obesity. High-calorie and high-fat food is accessible because of its low cost and immediate availability (Wright & Aronne, 2012). Genetic factors also impact obesity (Pinto et al., 2019) as well as various hormonal problems such as hypothyroidism, and external factors affecting the endocrine system (such as food or industrial drugs consumed by humans) (Barness et al., 2007). Social factors also contribute to the risk of obesity. Research shows that people are more likely to be obese if they have a friend, brother or spouse who has gained weight to the extent of obesity (Wright & Aronne, 2012). Thus, it is evident that the origin of obesity consists of interactions between environmental, biological, and genetic factors.

Obesity may be related to disturbed eating which involves a variety of unbalanced eating behaviors. Some of these behaviors are diet-related, such as an unsupervised diet that includes strict calorie intake, while other behaviors include unhealthy eating, such as consuming a large amount of high-fat foods while skipping meals. In addition, anorectic or bulimic behaviors such as taking laxatives or diet pills, vomiting, and periodicity of binge eating and dieting are also considered to be disturbed eating behaviors (Littleton & Ollendick, 2003).

It appears there is a phenomenological overlap between substance-related and addictive disorders and feeding and eating disorders, in that the need for 'control' plays a prominent role in the criteria for disorders within these two categories (Hebebrand et al., 2014). The response to food stimulates reward-related brain pathways, much like brain activity when consuming alcohol, drugs, and tobacco. These

pathways include the dopamine system and the opiate system. The cerebral causes of overeating and craving for food are similar to those of consuming addictive substances in that both stimulate intrusive thoughts and direct our attention to the desired goal, such as consuming addictive substances or consuming high calorie foods while a person is not hungry (Kavanagh et al., 2005; May et al., 2004).

Furthermore, brain imaging studies have shown an association between the Mesocorticolimbic pathways, associated with providing rewards and various cognitive processes, and overeating (Alcaro et al., 2007; Kelley & Berridge, 2002). This pathway has been previously linked to the term 'appetitive motivation', which means increasing behavioral orientation toward goals that have pleasant and positive hedonistic effects such as eating, drinking alcohol or having sex. The hedonistic effects can be related to one's subjective experience and emotional impact of action (Bozarth, 1994).

Previous studies have found that overweight individuals show greater brain activity in more extensive reward areas than thin individuals, and reduced brain activity in inhibitory areas in response to food images, especially high-calorie food (Yokum & Stice, 2013). Accordingly, it has been suggested that the tension between appetitive motivation and cognitive inhibition leads to a person's eating behavior, so that lack of control and goal-directed behavior of food consumption, especially calorie-rich food, which is of greater hedonistic value, will lead to weight gain, overweight and obesity (Appelhans, 2009; Nederkoorn et al., 2010; Nederkoorn et al., 2006).

Cognitive strategies for intervention in eating behaviors

Due to the many negative effects of obesity noted above, and the expansion of the phenomenon to the point of being defined as an epidemic in recent years, the need to develop weight loss treatment methods and maintain proper body weight has increased (Wadden, & Stunkard, 2002). One of these ways, which addresses the uncontrollable desire to eat foods of great calorific value, is a cognitive reappraisal (CR) exercise. CR interventions involve the person's conscious cognitive change of the meaning of the situation aiming to consequently change the emotional response to it (Giuliani et al., 2013). Hence, it may strengthen one's cognitive control when encountering high-calorie food, thereby weakening the appetitive motivation. This strategy has previously been supported by findings demonstrating that cognitive interventions contribute to a decrease in food cravings through active control of one's way of thinking about food (Giuliani et al., 2013; Werrij et al., 2009).

CR aims to change how one thinks about emotionally stimulating cues, such as high-calorie food cues. In most studies using brain imaging, the instructions for practicing this strategy are not detailed, however, Giuliani et al., 2013 describes the following procedures: (1) "Imagine that currently you are very replete, (2) focus on the negative consequences of eating this food (stomach ache or weight gain for example), (3) Remind yourself that you can keep this dish for later, (4) Imagine something bad happened to the dish (let's say someone sneezed on it)." Each participant had to choose one of this proposed CR strategies or create an alternative strategy that would be applicable in the real world and use it throughout the experiment. Subsequently, the researchers found that there was a decrease in the desire to eat high-

calorie food, with no significant difference between the strategies proposed by the research team and those created by the participants themselves (Giuliani et al., 2013).

Functional Magnetic Resonance Imaging (fMRI) studies of smokers and studies of people with normal BMI found that using CR when given the long-term negative effects of eating high-fat food has reduced the desire for high-fat food (Kober et al., 2010; Siep et al., 2012). In addition, using CR has been shown to increase activity in inhibitory areas (such as the Gyrus and Ventrolateral Prefrontal Cortex) in exposure to high-fat or sugar-rich food, and attenuate activity in attentional areas (such as the Precuneus and Posterior Cingulate Cortex). These findings suggest that CR can suppress appetitive motivation and reduce unhealthy food intake in overweight individuals (Stice et al., 2015; Yokum & Stice, 2013).

Changes in attentional bias as a measure of the impact of cognitive strategies

Attentional Bias (AB) is a state of automatic and excessive attention to specific stimulation (MacLeod & Matthews, 2012). Attention bias towards food is a specific case of AB, called Food Attentional Bias. Berridge (1996) proposed the model of food reward, which holds that unhealthy eating is a behavioral response to such FAB. According to this model, unhealthy food cues capture more attention as they are perceived as more attractive, rewarding, and tasteful (Polivy et al., 2008). FAB has been linked to people's inability to resist the temptation of food (Graham et al., 2011) suggesting that obese people will have greater FAB. FAB leads to faster processing of food-related information in obese individuals relative to non-obese individuals (Hendrikse et al., 2015).

In this study, we used the Visual Dot Probe (VDP) to assess FAB. This procedure is commonly used to measure AB toward various stimuli, such as smoking and alcohol (Ehrman et al., 2002; Townshend & Duka, 2001; See Methods section). A study that used the VDP procedure as an indicator of FAB, found that all participants exhibited FAB, but obese individuals showed an increased FAB compared to participants without obesity (Nijs et al., 2010a, 2010b). This suggests that the VDP task provides a sensitive measure of FAB (Hendrikse et al., 2015).

This study

The main goal of the current study was to examine in what ways FAB is modulated by cognitive-behavioral procedures used for regulating food consumption. To this end we tested participants' FAB before and after they performed a CR or a control procedure and analyzed their effects on FAB. Participants were divided into two groups: In the CR group, they performed a cognitive reappraisal procedure and in the control group they performed a neutral task (CN). All groups performed a computerized VDP task before and after the intervention. In this task, two stimuli were briefly presented on the screen and participants only watched them. These stimuli included the target stimulus – either a word or a picture of *food*, and a neutral stimulus, either a word or a picture of an *animal*. Immediately

after the word or picture disappeared, a dot appeared on the screen where either the target or the neutral stimulus had been presented. Participants were asked to press a key to indicate the location of the dot, and their reaction time (RT) was recorded. The difference between RT on compatible (the dot appeared in the same position as the food stimulus) and incompatible (the dot did not appear in the same position as the food stimulus) trials served as the FAB score.

Following Giuliani et al.'s (2013) study, in the intervention procedure, participants were required to write and memorize five sentences, while they were watching a set of pictures that included high-calorie appetizing food products. Participants in the CR group were instructed to write sentences about the negative consequences of eating high-calorie foods whereas participants in the CN group were required to write and memorize five neutral sentences about their day. Following the intervention procedure, all participants performed the VDP task again, with a different set of stimuli. In the last phase of the study the participants self-reported on demographics and eating behaviors.

We hypothesized that:

1. In the CR group, post intervention FAB scores will be lower than pre-intervention scores. In addition, following the intervention, the CR intervention group would show reduced FAB compared to the control group.
2. The CR intervention will have a greater impact on FAB levels among participants with higher disturbed eating behaviors than participants with lower disturbed eating behaviors.

Method

Participants

The study included 126 non-vegetarian non-vegan participants recruited from the community or from undergraduate students in an Israeli college earning course credit. The sample consisted of 35 men and 91 women. Participants were randomly assigned to the one of the intervention groups. The CR intervention group included 18 male and 49 women, with mean age 26.49 ± 5.57 ; mean BMI 24.25 ± 4.78 and mean score on EAT-26 $2.35 \pm .55$, and the CN group included 17 male and 42 women, with mean age 27.56 ± 6.14 ; mean BMI 24.45 ± 4.76 , and Mean score on EAT-26 $2.29 \pm .53$. There were no statistical differences between the groups in any of these variables.

Design and Procedure

The study was constructed as a 2X2 mixed-design experiment, manipulating the intervention (cognitive reappraisal (CR) or control (CN)) as a between participant variable and the FAB testing time (pre or post-intervention) as a within-participant variable. BMI and disturbed eating were used as additional predictors.

Participants were invited to take part in a study a perception and attention study related to food. In view of previous findings indicating that FAB may be increased by hunger (e.g., by fasting Stice et al., 2015; Yokum & Stice, 2013), participants were asked to eat about two hours before they took part in the study, but not during the last hour before they started their participation, and their compliance was verified. The study was individually conducted in a quiet room, and the session lasted about 40 minutes. Participants performed the tasks in the following order: (1) Pre-test VDP task (2) Intervention procedure (3) Post-test VDP task (4) Computerized questionnaire including Disturbed Eating demographics, self-reported BMI. At the end of the experiment, participants were provided with information about the study and the e-mail addresses of the authors for future inquiries.

Tools

Food Attention Bias score (FAB): The VDP task

To test FAB, a VDP task (following Hendrikse et al., 2015 and Kemps et al., 2014) comprised of two blocks was conducted one of them use pictures and the other words. In the picture block, each step in the VDP task included three phases (see Figure 1). In the first phase, a fixation cross appeared in the center of the screen for 500 milliseconds (ms.), and participants were asked to focus on it. Once they were focused, they pressed a key to move to next phase. On the second phase, two pictures appeared on the screen for 500 ms., such that on half the trials an animal picture was displayed above the center of the screen and a picture food below, on the other half the food picture was displayed above the center of the screen and the animal below. Participants were asked to watch the pictures, but they were not required to respond in any way. In the third phase, a dot was displayed on the screen either on the same spatial location where the food picture was previously displayed – in the *compatible* condition, or in the location where the animal picture appeared – in the *incompatible* condition. The order of compatible and incompatible trials was random. Participants were asked to respond as fast as possible to indicate the location of the dot by pressing the V key on the keyboard when the dot was at the bottom of the screen or the U key when the dot was at the top of the screen, and their reaction-time (RT) was recorded. The interval between steps was 1,000 milliseconds. In the word VDP block the same procedure was used, but instead of pictures, words of food and animals were presented. We decided to use both images and words because the literature was inconclusive as to which stimuli are more effective in eliciting FAB (Kemps et al., 2014). The order of the pictures and words blocks was randomized and counter-balanced between participants. Each participant took ten training steps before starting the pre-test phase to make sure the instructions were understood. Following the training, the pre-intervention test began, with five additional training steps followed by eighty test steps. The post-intervention FAB test that began following the intervention procedure was similar in all aspects but used different pictures and words. The FAB score was calculated from the participants' RT as the difference between RT on *incompatible* steps and RT on *compatible* steps.

Pictures. Forty pictures of foods and 40 pictures of animals were used for the picture FAB test (for a full list, please contact authors). Pictures of high-calorie foods such as croissants and hamburgers were selected from the materials of Bleichert et al. (2014). Pictures of favorable animals, typically not eaten in western cultures (e.g., parrot, hippo) were selected from Kemps et al.'s (2014) study. The animals were selected because, like food items, this category is generally considered attractive (Kemps et al., 2014). To verify that the pictures were valid and suitable for Israeli participants we conducted a pilot study in which participants (N=100) were asked to rate the pictures of the food and animals on three 1-7 scales, indicating (a) how clear was the picture; (b) to what extent it attracted attention; and (c) how appealing it is for eating. All food pictures were rated above 4 on the "appealing for eating" scale (except for one item with less than 4 but still higher than 3). By contrast, all animal pictures were rated below 3 on that scale, confirming that they were not associated with food.

Words. Forty words referring to high-calorie foods, such as fries and chocolate (Bleichert et al., 2014; Siep et al., 2012), and 40 words referring to favorable animals typically not eaten in western cultures (e.g., iguana) served for the word FAB-test. As the test was conducted in Hebrew, we could not use the English stimuli used in previous studies. Hence, we conducted a pilot to evaluate how appealing to eat they were. Participants (N=100 who did not participate in the main experiment) were presented with a list of 60 words of food and 60 words of animals and asked to rate them on a 1-7 scale indicating to what extent they were appealing for eating. Finally, the food pictures rated as highest on the appealing to eat scale, and the animal pictures rated as lowest were selected for the VDP task. The words were presented in black on a white background. They were displayed above each other horizontally centered at an equal distance (40 millimeters) from the center of the screen.

The 40 pictures and 40 words selected for the study were divided into two lists such that half the participants were presented with one list in the pre-test and the other one in the post-test, and the order was reversed for the other participants (For the full list, please contact authors. Appendix A details means and SDs, along with the t-tests values for the differences between the lists in terms of the pictures and words ratings (i.e., picture clarity, attention attraction appeal for eating and word frequency). The results show some differences between the lists, but as these differences were revealed only for the animals' stimuli, we did not recalibrate the lists.

Cognitive intervention procedures

Cognitive Reappraisal. Participants were instructed to write down five sentences about negative consequences of eating high-calorie foods related to health risk, body image etc. The experimenter gave them examples such as "This food is not healthy for me" or "I will regret eating this later on". Subsequently, they were presented with 5 pictures of high-calorie foods on the computer monitor and were asked to rehearse aloud the sentences while watching the pictures. They were then asked to rewrite the sentences repeatedly for 5 minutes. Then another set of high-calorie foods was displayed, and they had to rewrite the sentences again, and this cycle repeated 4 times for a duration of 20 minutes.

Control. In the control group participants were instructed to write neutral sentences relating to their day-to-day life, which were not emotionally stimulating. The experimenter gave them examples such as “Today I took the bus to school” or “I brushed my teeth when I got up this morning”. They were then asked to use the sentences suggested to them or make up their own and rewrite them repeatedly for 5 minutes.

Disturbed Eating

Disturbed eating was measured using the Eating Attitudes Test Questionnaire (EAT-26; Garner et al., 1982). The EAT-26 contains three sub scales: Diet (13 items such as: "I feel very guilty after eating"), Bulimia (7 items such as: " I had binge-eating episodes I feared I would not be able to stop") and Oral control (6 items such as: "I feel others would prefer I eat more"). Each item is rated on a 6-point Likert-type scale ranging from 1 (never) to 6 (always). We focus on the bulimia subscale because it reflects over eating, and may be expected to be more closely associated to FAB. The Hebrew version of EAT-26 has been found successful in distinguishing between people with or without eating disorders. Internal reliability for the original and Hebrew versions (Cronbach's alpha = 0.81 for the entire questionnaire; Koslowsky et al., 1992; Zohar et al., 2007) is comparable to previous findings (Garner et al., 1982 Cronbach's alpha =.83 for the entire questionnaire; Test-Retest reliability Cronbach's alpha =.80).

BMI

Participants height and weight were charted. BMI was calculated by dividing weight in Kilograms by height in meters squared.

Results

Data analysis was based only on the correct responses, incorrect responses (less than 5% per condition) were not included in the analysis. For each participant, the FAB score was calculated by subtracting the mean response times in the incompatible condition (the dot position was incompatible with the food position) from the mean response times in the compatible condition (the dot position was compatible with the food position), for the pre-test and for the post-test separately. As we did not hypothesize a difference between words and pictures N, and there was no significant difference between them in the FAB scores we averaged the scores across all stimuli to generate a united FAB score. The averages and standard deviations of the different experimental conditions are shown in Table 1.

Table 1
Average FAB scores pre- and post-intervention by intervention group

	CR Mean (SD) N=67	CN Mean (SD) N=59	ALL Mean (SD) N=126	$t_{(df)}$
Pre-test	1.55 (20.99)	-3.37 (20.87)	-.75 (21.00)	$t_{(124)}=-1.32, NS$
Post-test	-5.66 (20.93)	-.50 (17.28)	-3.25 (19.41)	$t_{(124)}=1.50, NS$

BMI ranged between 16.53-38.29 with a mean of 24.4 and SD=4.75. BMI was positively correlated with the bulimia subscale of the EAT-26 ($r=.33, p<.05$). No other correlations were found pre-intervention.

Effect of intervention procedure on FAB

Hypothesis 1: The CR group would show a reduction in FAB at the end of the intervention, compared to the CN group.

To examine that there were no differences between the groups before the intervention, a T-Test for independent samples was conducted on the pre-test FAB scores. Although the scores presented in Table 1 show a small difference, the T-Test shows that this difference was not significant. To test the hypothesis that the intervention (CR vs. CN) influenced FAB, we conducted a two-way mixed ANOVA on the FAB scores with time as a within-participant variable (pre/post intervention) and group as a between-participant variable (CR / CN). No main effect for time was found, and no main effect was found for group. Critically, the interaction between group and time was significant ($F_{(2,124)}=5.13, p<0.05$), as hypothesized. Post Hoc tests revealed a decrease in FAB in the CR group post-intervention compared to pre-intervention (difference=7.21 $p<.05$), in accordance with our hypothesis. However, no significant difference was found between pre- and post-interventions (difference=2.87) in the CN group (see Table 1), as expected.

Disturbed eating

Hypothesis 2: The CR intervention will have a greater impact on FAB levels among participants with higher disturbed eating behaviors than participants with lower disturbed eating behaviors, revealing an interaction between the intervention group (CR and CN) and

disturbed eating in their influence on the reduction in FAB following the intervention.

To test this hypothesis, we classified participants to high or low on the Disturbed Eating scale using a median split. A three-way ANOVA (time X intervention X Disturbed Eating) revealed no significant effect for the Disturbed Eating class, or for its interactions with time or intervention. Hence, we focused on the bulimia subscale of the EAT-26. We classified participants to high or low on the bulimia subscale using a median split and conducted a three-way ANOVA (time X intervention X bulimia). The analysis revealed a significant three-way interaction ($F_{(1,118)}=5.66, p<0.05$, see Figure 2). And a two-way interaction between time and group ($F_{(1,118)}=5.36, p<0.05$). To further understand this interaction regarding our hypothesis we conducted a two-way ANOVA for the CR group. The results show a significant interaction between time and bulimia class ($F_{(1,63)}=5.92, p<0.05$) with a larger intervention effect for the high bulimia class (difference=9.01) compared to the low bulimia class (difference=5.18), as can be seen in Figure 2.

Discussion

The purpose of the present study was to examine the effects of a cognitive regulation strategy on attentional bias toward food cues (FAB), and the susceptibility of participants with different levels of disturbed eating scores to such intervention. Previous studies in the field typically examined separately the relationship between cognitive strategies and changes in attention bias toward food (Giuliani et al., 2013; Kemps et al., 2014; Werrij et al., 2009), or between cognitive strategies and their relation to disturbed eating (Danner et al., 2012; McLean et al., 2010, 2011). The novelty of the present study is that it combines, in one experimental set, a study of the effect of CR on FAB and their relationship to disturbed eating. Moreover, while previous studies used either self-report measures or neurophysiological brain responses, we use the VDP task which is an objective, highly sensitive behavioral measure of FAB.

Our key hypothesis was that CR will reduce participants' FAB levels. This hypothesis was confirmed, and thus our study extends previous findings that were obtained in different methods (i.e. fMRI; Siep et al., 2012; Yokum, & Stice, 2013). While past studies have primarily focused on changes in cerebral activity which are not always easy to associate with particular behavior, the results of the current study indicate that CR strategy has a direct effect on human behavior. The CR strategy reduced FAB as reflected in the VDP task compared to the control group suggesting that such interventions can reduce attentional focus on fattening food. Critically, the negative FAB scores post-intervention indicate that participants looked more to animals than to food, suggesting an attentional avoidance behavior.

The study of Werthmann et al. (2011) indicates that people who are overweight tend to be more attentive to the stimuli that show food, but over time they refrain more from turning their attentions to these stimuli. This avoidance is deliberate, and it occurs to those people because of their desire to reduce their attraction to high-calorie food stimuli, which, despite their lust for it, is known to be harmful to them. Our findings suggest that the cognitive reappraisal procedure may have elicited a similar process, causing

participants in the CR group to deliberately divert attention from the high-calorie food stimuli, after reminding themselves the negative consequences of consuming such food.

The second hypothesis was that disturbed eating would moderate the relationship between CR and FAB. Although such general effect was not found, when we focused on the bulimia scale of the disturb eating questionnaire interesting findings were revealed. The bulimia sub-subscale of the EAT-26 is associated with over-eating (1982, Garner et al), and was found to moderate the relationship between CR and FAB. Participants high on bulimia were more susceptible to the intervention, as evidence by the larger pre/post intervention difference they exhibited compared to participants in the CN group. This finding suggests that for people with high levels of overeating, CR may help reduce FAB and, in turn, reduce food intake and weight gain. Danner et al., (2012) found that people with disturbed eating behaviors based on poor control ability, such as bulimia, made less use of cognitive strategies when compared to others. The use of CR involves restraint and control behaviors (Appelhans, 2009; McKinley & Hyde, 1996; Nederkoorn et al., 2006; Nederkoorn et al., 2010). The findings of the present study indicate that when people high on the bulimia sub-scale are instructed to use this strategy, it may increase their strategic use of restraint and control mechanisms.

This study aimed to demonstrate the use of VDP as a tool for assessing FAB and the factors that may moderate it. However further research is required for establishing our innovative findings. One important limitation of our study is that although we tried to recruit participants with a broad weight and BMI range, in practice, we found it difficult to reach many pathologically obese participants. Most of the participants in our study were at on the center of the BMI range (58%), and although we succeeded in recruiting some participants with high BMI values (i.e., overweight and obesity) it was only a small part of our sample (13%). This may explain why we did not get any evidence that the effect of the CR intervention was moderated by BMI. Future research on this topic should include more diverse populations in terms of BMI, especially overweight and obese individuals including more pronounced pathologies, such as eating disorders and obesity.

Another limitation of this study concerns the nature of the CR intervention. We instructed participants to produce five sentences that would make them less appreciative of the food pictures they were viewing. Participants created their own sentences, and we did not supervise these sentences. The advantage of this procedures is that it lets participants choose what they think would be most effective for them. The limitation, in terms of the research is that we have no way of knowing if they would have real value for them in everyday situations. Future studies should examine different sentences to try and underly what kind of sentences are most effective for CR.

Despite these limitations, the current study is innovating in demonstrating that that food related behaviors may be modulated cognitive strategies that may reduce attentional bias toward high-calorie foods, and even lead to attentional avoidance from such food. Future studies should extend this investigation to examine the effect of such CR-elicited attentional avoidance on the actual eating behavior, and test to what extent they reduce the consumption of fattening foods. In addition, future

studies should examine the effect of time on the effectivity of CR interventions. Here we focused on the immediate and short-term impact of CR on FAB; future research could extend the time frame of the pre/post testing to examine the impact of the CR intervention in the long-term.

In conclusion, the results of the present study have important theoretical implications highlighting the attentional mechanisms underlying food intake, and high calorie foods in particular. **Conclusions:** This study also has practical and clinical implications because using CR to change FAB levels may serve as an intervention to prevent unhealthy eating. The ability to use a relatively simple, easy-to-implement strategy with no financial cost is extremely important in an era in which individuals are constantly solicited to consume high calories food by a variety of stimuli and temptations for unhealthy food consumption. In addition, understanding which individuals respond better to CR can be another step in tailoring a customized plan, and may greatly contribute to coping with reducing the individual's FAB in order to help him maintain his weight.

List Of Abbreviations

Cognitive reappraisal (CR)

Food attentional bias (FAB)

Visual Dot Probe (VDP)

Control (CN)

Eating Attitudes Test Questionnaire (EAT-26)

Milliseconds (ms.)

Reaction time (RT)

Attentional Bias (AB)

Functional Magnetic Resonance Imaging (fMRI)

Body mass index (BMI)

Declarations

- **Ethics approval and consent to participate**

All ethical guidelines were adhered to and IRB approval was received.

- **Consent for publication**

All authors have given their consent for publication.

• Availability of data and materials

All data and materials are available upon request.

• Competing interests

We have no competing interests and have nothing to disclose.

• Funding

There is no funding to claim and authors have nothing to disclose.

• Authors' contributions

The corresponding author (Lilac Lev-Ari, PhD, ldlevvari@gmail.com) conceived and conducted the study and wrote parts of the manuscript. She also has full access to the data and has the right to publish it. All the authors participated in a meaningful way in the preparation of the manuscript. Dr. Hamutal Kreiner helped devise and construct the cognitive parts of the study and wrote significant parts of the manuscript. Mr. Omer Avni, a graduate student, helped conceive and build the study paradigm and recruited participants and did parts of the actual conducting of the study. Dr Lev-Ari performed all statistical analyses.

• Acknowledgements

We would like to acknowledge all of the students who helped devise and conduct this study (in alphabetical order): Gal Asiag, Lee Cohen, Zlil Gur, Shai Igra, Amit Shamgar and Tania Shapso
