Abstract

Prognosis and management of COVID-19 severity is a challenge even after months of the pandemic. Host plasma proteome alterations carry insights into the physiological alterations in response to the infection. Here we employed a mass spectrometry-based label-free quantitative proteomics approach to study alteration in plasma proteome in a cohort of 73 patients (20 COVID negative, 18 non-severe, and 33 severe) to understand the disease dynamics for addressing this challenge. Of the 1200 proteins detected in the patient plasma, 38 proteins were differentially expressed between non-severe and severe groups. The host proteins such as Angiotensinogen, apolipoprotein B, SERPINA3, SERPING1, and Fibrinogen gamma chain identified in LFQ analysis were further validated using targeted mass spectrometry assay. Utilizing our proteomics dataset, we identified multiple drugs that could inhibit the upregulated proteins involved in disease pathogenesis of these 2 FDA-approved drugs Selinexor and Ponatinib, which showed promise of being re-purposed for potential therapeutics of COVID-19. Plasma proteome identified significant dysregulation in the pathways related to peptidase activity, regulated exocytosis, blood coagulation, complement activation, leukocyte activation involved in immune response, and response to glucocorticoid biological processes during severe SARS-CoV-2 infection. Further, the results suggest that COVID-19 severity can be prognosticated using specific biomarkers of severity, and few of these proteins are excellent targets for re-purposed drugs.

1. Introduction

Unparalleled events have unfolded in the year 2020. A previously unknown infectious microbe has held life as we know it to ransom by triggering a raging pandemic of Coronavirus disease (COVID-19) sweeping across continents like a wildfire and much like a wildfire left behind a trail of more than a million dead and destruction of lives and livelihood of millions of others. The microbe that we now know as the Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2),¹ is a beta coronavirus that belongs to the order Nidovirales of the Coronaviridae family. Thus, the virus has the same lineage as other highly infectious viruses SARS-CoV and Middle East respiratory syndrome coronavirus (MERS-CoV) both have caused outbreaks in the preceding decades.² In humans, SARS-CoV-2 attaches to the Angiotensin-converting enzyme 2 (ACE2) receptor and infects the human respiratory tract and lungs, mostly leading to typical flu-like symptoms like dry cough, body ache, and fever.³ However, sometimes, it leads to acute respiratory distress syndrome. Patients of severe COVID-19 deteriorate to multi-organ dysfunction and death^{4,5} despite intense medical intervention. However, although SARS-CoV-2 primarily targets the respiratory tract and lung, an increasing body of work has shown the virus to infect other organs like the gastrointestinal tract, liver, kidney, cardiac muscles, central nervous system, musculoskeletal system, and even reproductive system in males.^{6,7}

The diagnosis of the disease has been accurate and widespread. This was possible due to increased availability and deployment of RT-PCR assays,⁸ or serological test kits, and scaling up of testing rates globally.⁹ However, the prognosis of the disease remains a challenge. This is because the precise

pathophysiological pathways that get perturbed during the disease's progression to severity remain mostly unexplored.

Blood is the only body fluid that reaches virtually all organ systems of our body and potentially carries information of perturbations in their physiology. Further, owing to its minimally invasive nature, it has been the mainstay of several diagnostic tests used for assaying multiple parameters to assess the physiological state of the human body. Indeed, blood is the clinician's biofluid of choice to understand physiological aberrances, and thus blood plasma proteome is an excellent source for assessing host-response.¹⁰

The sensitivity and high throughput nature of modern-day mass–spectrometry has allowed the scientist to detect even the faintest of agitations in host physiology.¹¹ For our study, we chose to apply a deep proteomics strategy to delineate the systems-wide perturbations brought about by SARS-COV-2 infection in their human host during non –severe and severe COVID-19. We surveyed the host plasma proteome from blood collected from a large cohort of 73 patients (Supplementary Table S1) of varying COVID-19 severity during their active infection phase.

We could uncover the pathological processes that turn a non–severe COVID-19 into a severe form. A mere 38 differentially expressed proteins could lead to the transition from non-severe to severe COVID-19. Dysregulations in the pathways, especially relating to inflammatory pathways, complement activation, and blood clotting, are crucial and can prognosticate the disease's severity. Further, to validate our findings, we conducted MRM studies on unique peptides.

Finally, armed with our information of the differentially expressed proteome, we used a customized drug library for *in silico* docking studies on over-expressed host proteins to screen potential drugs for the management of the disease. The analysis revealed two FDA-approved drugs with the best binding affinity towards the therapeutic targets reported in the study.

These salient outcomes provide valued information on plasma biomarkers associated with the severity of COVID-19 and unravel the mechanistic pathways of the pathogenesis of SARS-CoV-2 infection. Further, the potential FDA-approved drugs showing inhibition towards the marker proteins could be validated on cell-line based studies.

2. Material And Methods

2.1 Sample and clinical details

For this study, we procured plasma samples from 73 patients who visited Kasturba Hospital for Infectious Diseases, Mumbai. All plasma samples were collected with approval from the Institute Ethics Committee, IIT Bombay, and Kasturba Hospital for Infectious Diseases, Institutional Review Board. Based on RT-PCR results, these patients were assigned as COVID-19 positive and COVID-19 negative. Depending on the clinical symptoms, positive patients as advised by clinicians were further grouped into severe

(patients with mechanical ventilation and having severe symptoms of acute respiratory distress, bilateral pneumonia) and non-severe (patients having mild symptoms of cough, fever, fatigue, and breathlessness without invasive ventilation)

For plasma proteomic analysis of COVID-19 infected patients, 20 negative, 18 non-severe, and 33 severe cases were taken forward (Supplementary Table 1). Kasturba Hospital collected approximately 2 mL of whole blood for biochemical and serological tests from COVID-19, RT-PCR confirmed and suspected patients. Whole blood was collected in a sterile vacutainer by trained medical practitioners under aseptic conditions. After Biochemical tests were performed, leftover blood (~1 mL) was collected and centrifuged at 3000 rpm for 10 minutes to separate plasma. The separated plasma was then incubated at 56°C for 30 mins for viral inactivation and further stored at -80°C in cryovials. For the MRM validation experiment, 12 COVID-19 positive patient samples were taken forward.

2.2 Proteomics analysis

All plasma samples were depleted to improve the detectability of low-abundance plasma proteins. In our study, plasma samples were first subjected to Pierce™ top 12 abundant protein depletion spin column (ThermoFisher Scientific) and incubated for 1 hour under rocking motion. Samples were centrifuged at 1500g for 2min to obtain the low abundant plasma protein. To concentrate the sample, it was evaporated to 1/4th of its initial volume. Then the sample was stored at -80°C for further processing. The depleted plasma sample was taken forward for quantification by Bradford assay, taking BSA as standard. To 30µg of the depleted plasma sample, 6M of urea lysis buffer was added, followed by six times dilution with ammonium bicarbonate. Before digestion of the protein, the plasma protein extract was reduced with TCEP (final concentration 20mM) at 37°C for 1 hour and then alkylated with iodoacetamide (final concentration 40mM) for 15min under dark condition. Protein was finally subjected to enzymatic digestion by Trypsin at an enzyme/substrate ratio of 1:30 for 16 hours at 37°C. The digested peptide was then vacuum dried and reconstituted in 1% (v/v) FA. To reduce the salt concentration in the digested peptide, it was cleaned up using the C18 column obeying the reverse phase column chromatography principle. The cleaned peptide was further dried and dissolved in 1% (v/v) (FA). The peptide concentration was calculated using the Scopes method from its O.D. value at 205nm and 280nm. 1µg peptide of each sample was run in Orbitrap Fusion Tribrid Mass Spectrometer (Thermo Fischer Scientific) with an easy nano-LC 1200 system with a gradient of 80% ACN and 0.1% FA for 120 min with blanks after every sample. BSA was run at the starting and endpoint of each set of the run to check the instrument quality. All samples were loaded onto the LC column at a flow rate of 300 nL/min. Mass spectrometric data acquisition was done in data-dependent acquisition mode with a mass scan range of 375-1700 m/z and a mass resolution of 60,000. A mass window of 10 ppm was set with a dynamic exclusion of 40s. All MS/MS data was acquired by the High energy Collision Dissociation method of fragmentation, and data acquisition was done using Thermo Thermo Xcalibur software version 4.0.

2.3 Proteomics data and pathway analysis

The raw datasets were processed with MaxQuant (v1.6.6.0) against the Human Swiss-Prot database (downloaded on 09.07.2020), searched with the built-in Andromeda Search Engine of MaxQuant.¹² Raw files were processed within Label-Free-Quantification (LFQ) parameters setting label-type as "standard" with a multiplicity of 1. The Orbitrap was set to Orbitrap Fusion mode. Trypsin was used for digestion with a maximum missed cleavage of 2. Carbamidomethylation of Cysteine (+57.021464 Da) was set as the fixed modification, whereas oxidation of Methionine (+15.994915 Da) was set as the variable modification. The False-Discovery-Rate (FDR) was set to 1% for the protein and peptide levels to ensure high protein detection/identification reliability. Decoy mode was set to "reverse", and the type of identified peptides was set to "unique+razor".

A sample wise correlation analysis of 74 samples was performed to understand the data quality, and three samples were removed. Proteomic data of 71 samples were taken forward to perform missing values imputation using the k-nearest neighbors (KNN) algorithm in Metaboanalyst.¹³ Statistical analysis and data visualization were carried out in Python and Microsoft excel. The significant differentially expressed proteins were determined using Welch's t-test where p values less than 0.05 was used as a cut-off. The biological pathway analysis was done using Metascape for GO enrichment analysis¹⁴, whereas String (Version 11.0)¹⁵ was used to prepare the protein-protein interaction (PPI) network.

2.4 Targeted proteomics by Multiple Reaction Monitoring Assay

The proteins found to be of statistical significance and showed upregulation in COVID-19 Severe compared with COVID-19 Non-severe and COVID-19 Negative in the LFQ data were selected and used for a targeted MRM study. The list of transitions was prepared for unique peptides of these selected proteins using Skyline (Ver 20.2.1.286). The missed cleavage criterion was 0, precursor charges +2, +3, and product charges +1, +2 with y ion transitions (from ion 3 to last ion -1) were included. Pools of each group of COVID-19 samples (positive and negative) were run against all the generated transitions and based on the data derived from it, and a list was finalized. The list thus formed consisted of 35 peptides from 13 proteins. This list included a spiked-in synthetic peptide (FEDGVLDPDYPR) essential for monitoring the consistency of the mass spectrometry runs (with a heavy labeled C-terminal Arginine). For the experiment, a Vanquish UHPLC system (ThermoFisher Scientific, USA) connected to a TSQ Altis mass spectrometer (ThermoFisher Scientific, USA) was used. The peptides were separated using a Hypersil Gold C18 column 1.9 μ m, 100 X 2.1 mm (ThermoFisher Scientific, USA) at a flow rate of .45 ml/min for a total time of 10 minutes. The binary buffer system used was 0.1% FA as the buffer A and 80% ACN in 0.1% FA as the buffer B. Approximately 1 μ g of BSA was also run with the samples to check uniformity in the instrument response.

A batch of samples that included six severe and six non-severe COVID-19 samples were run in duplicates against the above mentioned 35 peptides list. The first and second replicates were run two days apart to establish reproducibility. After the data was acquired, the raw files were imported into Skyline, and peaks were annotated with the help of a library. The library was built from the in-house LFQ data of COVID-19 samples.

2.5 Molecular docking

Differentially expressed proteins from our proteomic study have been taken forward for in-silico docking studies where we retrieved the complete crystal structures of the proteins available from Protein Data Bank (PDB).¹⁶ Known inhibitors were searched in the literature against the selected proteins, and they are termed as control inhibitors, and for each control, binding affinity (kcal/mol) was documented. We prepared a library of 58 small molecular components, among which 30 are already FDA approved, nine are in clinical trials, and nineteen are in pre-clinical phase trials. SDF files for each of the components were downloaded from the ZINC 15 database.¹⁷ The proteins having a complete crystal structure and known inhibitors were taken forward in this study, where each of them is docked against the library along with their respective controls. We used Autodock Vina 1.1.2 (Trott,O., Olson, 2019) to perform the docking experiment, which was inbuilt in PyRx software (<https://pyrx.sourceforge.io/>). After loading the .pdb structure of proteins, they were first converted to a macromolecule via Autodock tools. Similarly, SDF files for the selected drugs were converted to PDBQT format, which is a readable file format for Autodock Vina, using the open babel tool. In our blind docking method, the exhaustiveness was set to 50 while instead of choosing a particularly active site, the whole protein was consumed into the grid box. The docking output files were split into individual poses where the pose having the lowest binding energy was taken forward for further analysis. Finally, the Docked structures were visualized using PyMOL (Version 2.4) and Discovery Studio Visualizer Software (Version 4.0) and checked for the binding pockets for the drugs in the library. Additionally, the protein-ligand interaction profiler (PLIP) server was used to calculate the number and types of interactions between the protein and the drugs.¹⁸

3. Results

3.1 Deep proteomic analysis of patient plasma

We performed label-free quantification of a total of 74 depleted plasma samples, out of which 20 were negative, 18 were non-severe, and 36 were severe (Figure 1A). Figure 1 (B-F) depicts the schematic workflow of label-free quantification under discovery proteomics, illustrates the overview of statistical data analysis, shows the summary of synthetic peptide peaks after Multiple Reaction Monitoring (MRM) under validation proteomics, represents the outline of biological network analysis and docking study respectively. The correlation matrix of the total 74 samples is shown in Supplementary figure 1. The mass-spectrometry setting for the label-free quantification is shown in Supplementary figure 2. The LFQ analysis of 74 samples provides a total of 1206 proteins. A list of 278 missing value imputed proteins from 71 samples was taken forward for the partial least squares-discriminant analysis (PLSDA) for an overall assessment of the difference between the COVID-19 positive and COVID-19 negative sample cohort. The two sample cohorts were found segregating in two separate clusters shown in Figure 1G. The statistical analysis between the COVID-19 positive and COVID-19 negative cohort provides a list of 27 significant differentially expressed proteins, which has been represented in the form of a volcano plot in Figure 1H and a heatmap in Figure 1J (Supplementary Table S2). We identified proteins such as von Willebrand factor (VWF), Haptoglobin-related protein (HPR), Glutathione peroxidase 3 (GPX3), Alpha-2-

macroglobulin (A2M), Carbonic anhydrase 2 (CA2), Protein S100-A8 (S100A8), Carboxypeptidase B2 (CPB2), Heparin cofactor 2 (SERPIND1), Fibrinogen gamma chain (FGG), Profilin-1 (PFN1) and Serum amyloid A-4 protein (SAA4) to be significantly upregulated in the COVID-19 positive patients. The proteins such as Lymphatic vessel endothelial hyaluronic acid receptor 1 (LYVE1), Intercellular adhesion molecule 1 (ICAM1), Macrophage migration inhibitory factor (MIF), Histidine-rich glycoprotein (HRG), IgGfc-binding protein (FCGBP), Immunoglobulin heavy variable 3-15 (IGHV3-15) and Insulin-like growth factor-binding protein 3 (IGFBP3) are significantly downregulated in the COVID-19 positive patients. The violin plot of few dysregulated proteins SERPIND1, VWF, and MIF protein are shown in Figure 11. We have also found a protein Cadherin EGF LAG seven-pass G-type receptor 2 (CELSR2), which is exceptionally absent in all the COVID-19 negative samples but present in COVID-19 positive samples. The identification of CELSR2 protein in COVID-19 positive is also exciting as it is present in 5 out of 18 non-severe samples whereas found in 26 samples out of 33 severe samples.

Further, this study has also investigated the proteomic alteration between the Non-severe and Severe cohort, which provides a list of 38 significantly differentially expressed proteins (Supplementary Table S3). Figure 2A represents a heatmap of the top 25 differentially expressed proteins in context to the Severe and Non-Severe cohort. A list of 287 missing value imputed proteins was taken forward for the partial least squares-discriminant analysis (PLSDA) for an overall assessment of the difference between the Severe and Non-severe cohort. The two sample cohorts were found segregating in two separate clusters except for Sample P93, P30, and P106, which clustered closer to the opposite cohort (Figure 2B). Figure 2C depicts the significant DEPs in the form of a Volcano plot. The proteins such as Kallistatin (SERPINA4), Serum amyloid P-component (APCS), Protein S100-A8 (S100A8), Fibrinogen gamma chain (FGG), Corticosteroid-binding globulin (SERPINA6), and Alpha-1-antichymotrypsin (SERPINA3) were found to be upregulated in the severe cohort whereas proteins such as Complement factor D (CFD), Monocyte differentiation antigen (CD14), Complement component C8 alpha chain (C8A), Apolipoprotein (LPA) and Apolipoprotein M (APOM) were found to be downregulated in the severe when compared to non-severe patients. Supplementary figure S3 represents the top 25 differentially expressed proteins of Severe and Negative in the form of Heatmap and depicts the PLSDA clustering of the Severe versus Negative patients.

3.2 MRM analysis of proteins overexpressed in severe COVID-19

The MRM study aimed to validate the differentially regulated proteins found between COVID-19 severe and non-severe samples from the LFQ data. The BSA as QC standard to monitor day-wise instrument response is shown in Supplementary figure S4. To establish that all the injections gave the more or less same response, we spiked in an equal amount of a heavy labeled synthetic peptide (FEDGVLDPDYPR) in all samples. The uniform peak areas for this peptide, as shown in Supplementary figure S5, establishes the same. Even duplicates run on separate days showed comparable peak areas with very low CV. Based on the response of the differentially regulated peptides, the list was further refined to keep only peptides showing significant dysregulation (adjusted p values below 0.05) between severe and non-severe. For this, the peaks were annotated, and transitions were refined according to the library match to give dotp

values for all peptides. A dotp value is a measure of the match between the experimental peak and the library fragmentation patterns. Thus, the refined list had 183 transitions belonging to 28 peptides of 9 host proteins and 1 synthetic peptide. List of peptide sequences and transitions of proteins that showed differential regulation between COVID-19 non-severe and severe patient samples shown in Supplementary Table S4. Using the MS stats external tools in Skyline, we determined that proteins AGT, APOB, SERPINA3, FGG, and SEPRING1 have 3 or more than 3 peptides that show a peak area fold change more than 3 and adjusted p-value less than 0.05 at a confidence of 95-99% (Figure 3). This validates that for the given set of samples, these proteins are showing statistically significant overexpression in COVID-19 severe patients than in COVID-19 non-severe patients (refer to the data availability section for the Skyline files).

3.3 Biological Pathway and Network analysis of differentially expressed protein in Severe Vs. Non-severe comparison

We also identified the enriched biological processes for the 38 dysregulated proteins in COVID-19 severe compared to COVID-19 non-severe patients. The biological processes, enriched proteins were shown in the form of protein-protein interaction. Few proteins have been shown in the form of a violin plot (Figure 4A). Figure 4B shows a network of enriched terms colored by clusters, where nodes that share the same clusters are typically close to each other. We identified the biological process such as regulation of peptidase activity, regulated exocytosis, extracellular structure organization, blood coagulation, fibrin clot formation, complement activation, classical pathway, leukocyte activation involved in immune response, and Response to glucocorticoid process to be enriched in COVID-19 severe patients. The list of proteins expressed in these pathways is shown in Supplementary Table S5.

3.4 In-silico screening of drugs against differentially expressed proteins

We have performed in silico molecular docking of significantly altered proteins with the library of 58 drugs (Supplementary table 6A-E). Out of 58 drugs, 30 drugs are FDA approved, nine drugs are clinically approved, and 19 drugs are pre-clinical approved. We have identified positive control drugs for each protein from the literature, which is a known inhibitor of the protein. Positive control drug gives us a possible cut-off for the docking score. After docking, we have used two criteria for selecting the drugs for the protein. Firstly, the drug's binding energy should be equal to or higher than that of the control inhibitor. Secondly, the drug's binding pocket should be similar to the control drug. For COVID-19 non-severe vs. severe comparison, we have docked five significant proteins, which are Heparin cofactor 2, Thyroxine-binding globulin, Angiotensinogen, Carbonic Anhydrase-1, and Carbonic Anhydrase-2.

Heparin cofactor 2 (SERPIN D1) is a protein of 499 amino acid long peptide, which binds with the drug Sulodexide with a binding affinity of -7.1 kcal/mol and hence it is taken as a control drug (Supplementary figure S6A). When docked with the customized drug library, we find four FDA approved drugs that bind to a similar binding pocket as the control drug and have better binding affinity than the Sulodexide, namely, Selinexor (-8.7 kcal/mol), Ponatinib (-8.4 kcal/mol), EGCG (-7.7 kcal/mol) and Nafamostat (-8.1 kcal/mol). Another protein Thyroxine-binding globulin (SERPIN A7) is a protein with 415 amino acids. It

showed a binding affinity of -7.4 kcal/mol with the drug Tamoxifen which is a well-known inhibitor of the protein; hence we have used it as a control inhibitor of the protein (Supplementary figure S6B). From the customized drug library, SERPIN A7 has bound to Selinexor and Ponatinib with a binding affinity of -9.3 kcal/mol (Figure 6B). 2D interaction diagram of Selinexor docked with SERPIN A7 shows the amino acids Y20, and R381 forms potential Hydrogen bonds at the binding site (Figure 6A). Angiotensinogen, a 485 amino acids long protein is; binds with the Irbesartan with a binding affinity of -8.4 kcal/mol. It is a known inhibitor of the protein, so we have used it as a control drug (Supplementary figure S6C). Angiotensinogen binds to the drug ML-240, which a pre-clinical approved drug with a binding affinity of -8.9 kcal/mol. This is the only drug we have identified in our study to target Angiotensinogen. We have also performed docking of Carbonic Anhydrase-1 (261 amino acid length) and Carbonic Anhydrase-2 (260 amino acid length). Small molecule Topiramate binds with Carbonic Anhydrase-1 with a binding affinity of -9.2 kcal/mol (Supplementary figure S6D), and Acetazolamide binds with Carbonic Anhydrase-2 with a binding affinity of -6.3 kcal/mol (Supplementary figure S6E); they are used as control drug for respective proteins. Our study identified EGCG as the only FDA-approved drug that can be used to target Carbonic Anhydrase-1 (with binding affinity -9.5 kcal/mol) and Nafamostat (with binding affinity -8.2 kcal/mol) to target Carbonic Anhydrase-2. Four proteins from COVID-19 positive vs. negative comparison were used for molecular docking, which are Protein S100 A9, Carboxy Peptidase B2, Glutathione S-transferase omega-1, and 6-Phosphogluconate dehydrogenase.

We found that the Rapamycin drug can be used to target all 4 proteins as it is binding with the proteins with higher Binding affinity than their respective control drug and the binding pocket is also the same as the control drug. The first protein is Protein S100 A9, which is a small protein with 114 amino acids. We have used Tasquinimod as a control inhibitor as it binds with the protein with a binding affinity of -7.5 kcal/mol (Supplementary figure S6F). Using the above-mentioned criteria to select drugs, we have identified Protein S100 A9 can be targeted using two FDA approved drugs: Selinexor, which also binds to the protein with a binding affinity of -7.5 kcal/mol and another drug is Rapamycin, which is an mTOR inhibitor, it binds to the protein with a binding affinity of -8.2 kcal/mol. Carboxy Peptidase B2 is a 423 amino acid long protein. We have used Anabaenopeptin F as a control drug, and it binds with the protein with a binding affinity of -8.3 kcal/mol (Supplementary figure S6G). From our docking studies, we have identified 3 FDA-approved drugs Rapamycin (binding affinity -8.7 kcal/mol), Dabrafenib (binding affinity -8.8 kcal/mol), and Daunorubicin (binding affinity -8.6 kcal/mol), which can be used to target Carboxy Peptidase B2. Glutathione S-transferase omega-1 is a protein with 241 amino acids; CMFDA is a known inhibitor from literature. We have used CMFDA as a control drug. It binds to the GSTO-1 with a binding affinity of -8.3 kcal/mol (Supplementary figure S6H).

Four FDA approved drugs from our customized drug library can be used to target GSTO-1, which are Rapamycin (binding affinity -8.8 kcal/mol), Selinexor (binding affinity -8.6 kcal/mol), Ponatinib (binding affinity -9.1 kcal/mol), and Siltinasertib (binding affinity -8.3 kcal/mol). 6-Phosphogluconate dehydrogenase is a protein with 483 amino acids. We have used Physcion as a control drug; it binds with 6-PGDH 1 with a binding affinity of -7.0 kcal/mol (Supplementary figure S6I). Six FDA approved drugs from our customized drug library can be used to target 6-PGDH, which are Rapamycin (binding affinity

-8.8 kcal/mol), Selinexor (binding affinity -8.5 kcal/mol), Ponatinib (binding affinity -10.3 kcal/mol), Siltitasertib (binding affinity -7.7 kcal/mol), Daunorubicin (binding affinity -8.4 kcal/mol) and Dabrafenib (binding affinity -8.6 kcal/mol). We have found Rapamycin, an already approved drug for organ transplant rejection, binds to all four significantly upregulated proteins of COVID-19 positive vs. negative comparison from our molecular docking analysis. We have also found that Selinexor, an exportin antagonist, is approved for multiple myeloma, and Ponatinib, a tyrosine kinase inhibitor, is approved for Chronic Myeloid Leukemia (CML), can be used to target proteins. From COVID-19 positive vs. negative comparison and non-severe vs. severe comparison as it has shown to inhibit proteins from both the comparison. Another drug Pevonedistat, a clinically approved drug, can also be explored in the future to target COVID-19 as it has also been shown to inhibit proteins from both the comparison.

4. Discussion

Nasopharyngeal swab samples and serological tests are being routinely used in clinics to detect SARS-CoV-2 infection diagnosis; however, biomarkers for prognosis of the disease before it could lead to fatal symptoms are yet to be found. Understanding the host response towards the viral infection might provide important clues on the progression of the disease from non-severe to severity. A proteomics approach was applied for an in-depth understanding of the disease mechanism. Few studies have already reported differences in the level of blood-based proteins such as lactate dehydrogenase (LDH), d-dimers, and inflammatory markers such as C-reactive protein (CRP), ferritin, and fibrinogen in COVID-19 patients.^{19,20} One specific forte of our study is the in-depth profiling of plasma proteome from a cohort of COVID-19 patients (n = 73), facilitating the robust and statistically significant evaluation of differential expression between non-severe and severe disease groups. The Indian subcontinent being reasonably unscathed by the severity of the pandemic, reporting a few of the lowest case fatality rates per million,²¹ our study holds importance in understanding the biology associated with the same.

Deep proteome comparison between COVID-19 positive and COVID-19 negative patients who exhibited symptoms similar to COVID-19 revealed a subset of proteins that differentiates COVID-19 from other febrile respiratory maladies. Of importance was the upregulation of the von Willebrand factor (VWF). Animal studies have shown that increased VWF might be due to hypoxic conditions in the lung endothelial cells²²; however, this induces a risk of arterial or venous thrombosis since it directly promotes the thrombotic process during inflammation.²³ The increase in Haptoglobin-related protein (HPR) is also found in cases of idiopathic pulmonary fibrosis²⁴ and as a factor of non-bacterial pneumonia²⁵ thus may act as a biomarker of lung trauma. Carboxypeptidase B2 has anti-inflammatory and anti-fibrinolytic effects. Its increase in this cohort indicates the natural response to systemic inflammation brought about by COVID-19.²⁶ Another protein Profilin-1 (PFN1) overexpression implicated in the vascular hyperpermeability, vascular Hypertrophy can perhaps explain the aberrant physiology of COVID-19 patients. These apart acute phase response proteins were like SAA-4 and S100A8 were also upregulated in response to COVID-19.

Interestingly, however, the protein Lymphatic vessel endothelial hyaluronic acid receptor 1 (LYVE1) was downregulated and might indicate liver injury²⁷. At the same time, attenuated Histidine-rich glycoprotein (HRG) expression might explain the altered hemostasis in the patients.²⁸ However there lies a caveat, most of these patients were under medications the results might also be due to the ongoing therapies than the disease itself.

In our plasma deep proteome study of non-severe vs. severe patients, we observed that only 38 were differentially expressed proteins such as FGG, S100A8, VWF, SAA4, SERPIND1, and SERPINA6 to be upregulated in the COVID-19 positive patients while interestingly, the mitochondrial 60 kDa heat shock protein, HSPD1 was only expressed in the severe patients. It has been already reported that high levels of circulatory HSPD1 are associated with cardiac failures.²⁹ Therefore increased HSPD1 in severe patients can act as a clinical biomarker of cardiac malfunction in the severe group. Also, our results indicated an increase in plasma Cholinesterase (BCHE) in the severe group, which is upregulated in patients suffering from mild ischemic stroke.³⁰ These findings thus implicate severe COVID-19 associated risk of cardiac and CNS injury that has been already reported by clinicians, and these biomarkers could help prognosis of the threat.

The plasma levels of carbonic anhydrase 1 (CA1) was found to be substantially elevated in the severe group. Increased carbonic anhydrase has been found to mediate hemorrhagic retinal and cerebral vascular permeability.³¹ The ramifications of increased CA1 are also substantiated by earlier reports on a cohort study of sepsis secondary to pneumonia³², where it was found to be upregulated during sepsis. Moreover, the role of increased CA1 in the worsening of ischemic diabetic cardiomyopathy also paints a rather gloomy picture of the cardiac sequelae of COVID-19, especially in diabetic patients³³ and might also contribute to the increased fatality of diabetic patients.³⁴

The protein Fibrinogen (FGG) was also found to be upregulated in severe patients when compared to non-severe. FGG is an oligomeric glycoprotein produced in the liver and secreted in the blood. The increased fibrin formation and breakdown correlated with the high level of D-dimers observed in the COVID-19 patients with the worst outcomes.³⁵ The increasing level of FGG in severe might be due to liver injury, impairing hepatic fibrinogen secretion with acquired fibrinogen storage disease.³⁶ The protein S100A8 (calgranulin A/myeloid-related protein 8) belongs to the group of alarmins or damage-associated molecular patterns (DAMPs), which are released in response to stress against the microbial infection that leads to exacerbating the inflammatory response. Chen et al. and his co-workers reported that the level of S100A8 positively correlated with the C_t value and oxygen demand, indicating the severity of the acute respiratory distress (ARDs) in COVID-19 patients.³⁷ A recent study showed that severe COVID-19 patients release massive amounts of S100A8, which is accompanied by changes in monocytes and neutrophil subsets.³⁸ The protein AGT was found to be significantly upregulated in severe patients as compared to the non-severe. Angiotensinogen (AGT) is a component of the renin-angiotensin system (RAS), a substrate of renin that regulates blood pressure and fluid balance. The dysregulation of AGT and RAS might lead to acute lung injury and acute respiratory distress leading to a severe prognosis.³⁹

Apolipoprotein B-100 (APOB) is involved in lipid transport and low-density lipoprotein (LDL) catabolism. The high levels of APOB in the plasma might be an indicator of significant cardiovascular manifestation seen in COVID-19 infected severe patients.⁴⁰ These results are consistent with previous findings⁴¹ on COVID-19 patient sera, which had identified dysregulation of multiple apolipoproteins. Several serine protease inhibitors (SERPINs) such as SERPING1 and SERPINA3 were also identified to be upregulated in severe patients. The increasing level of SERPINs, an acute-phase protein, positively correlates and associates with a high level of IL-6 seen in severe patients.⁴² The validation study by MRM based assay could specifically detect AGT, FGG, APOB, SERPING1, and SERPINA3 host peptides in COVID-19 patients using. The mass spectrometry-based detection of host peptides used in our study can be used in the clinics for the prognosis of disease severity.

A subset of proteins was also downregulated in the severe group. The protein peptidase inhibitor 16 (PI16) was severely downregulated (FC= -2.45, P <0.005). It concurs well with the previous studies wherein it has been shown that while PI16 protective role against atherosclerosis, PI16 inhibition by circulating inflammatory cytokines that act through the NF- κ B signaling pathway.⁴³ These results demonstrate the pathogenesis of cardiac maladies in severe COVID-19 patients.⁴⁴ Patients with severe COVID-19 often report lower platelet count.⁴⁵ Our studies have demonstrated that a crucial factor in platelet biogenesis TPM4⁴⁶ is inhibited (FC-1.94, P < 0.001) in severe cases, thereby providing novel biological insight into COVID-19 severity. Another ubiquitously present protein β II spectrin was found to be downregulated in severe COVID-19, given that inadequate β II spectrin might precipitate into arrhythmia, heart failure, or even neurodegeneration⁴⁷ the findings hold much importance. Two proteins, namely APOM, which is known to protect the lungs and kidneys from injuries⁴⁸ and APOA2, were also downregulated; similar observations were previously reported.⁴¹

Functional enrichment analysis of the 38 differentially expressed proteins in severe vs. non-severe cohort revealed that these proteins are enriched in pathways related to blood coagulation, fibrin clot formation, complement system, leukocyte activation, regulation of peptidase activity, regulated exocytosis, and extracellular structure organization, among others. Proteins like A2M, SERPINA4, SERPINA3, SERPING1, and FGG that are involved in regulated exocytosis of platelets were upregulated in the severe cohort suggesting an increased consumption of platelets. This could be a possible reason for the lower platelet count (clinically called thrombocytopenia) commonly reported in many severe cases of COVID-19,⁴⁹ which is also associated with coagulation abnormalities, disease severity, and mortality.⁵⁰⁻⁵² There is enough evidence to suggest that platelets have potent immune and inflammatory effector functions aside from their role in hemostasis. Interaction between viruses and platelets has been known to stimulate platelet degranulation leading to the release of a variety of cytokines and chemokines.^{53,54} They also directly interact with leucocytes and endothelial cells to trigger and modulate inflammatory reactions and immune responses.⁵⁴ Thus, platelet hyperactivity due to the upregulation of these proteins correlates with the over-exuberant host inflammatory response as COVID-19 progresses from non-severe to severe.

Many of the peptidase activity regulator proteins, including SERPINA4, SERPING1, SERPINA3, SERPIND1, and A2M, are involved in blood coagulation and inflammation pathways. SERPINA4 is an inhibitor of the kallikrein-kinin system involved in coagulation and inflammation.^{55,56} SERPING1 is an inhibitor of the classical pathway of the complement system as well as of several proteins involved in blood coagulation.⁵⁷ SERPIN A3 is a significant inhibitor of cathepsin G, a key proteolytic enzyme and inflammatory effector released by neutrophils.⁵⁸ A2M is an inhibitor of a variety of proteases involved in blood coagulation and inflammation including thrombin, kallikrein, plasmin, and cathepsin G;⁵⁹ SERPIND1 regulates blood clot formation by inhibiting thrombin.⁶⁰ Moreover, FGG or fibrinogen gamma chain is a component of the clotting factor fibrinogen, promoting tissue repair. High fibrinogen levels are associated with bleeding and thrombosis and correlate with the increased erythrocyte sedimentation rate (ESR) observed in severe cases.^{61,62} COVID-19 associated coagulopathy is common in severe patients,⁶³ while overt disseminated intravascular coagulopathy, a critical condition characterized by abnormal blood clotting and bleeding, is observed in most the critically ill patients who do not survive.^{64,65} These thrombotic complications can be characterized by dysregulation of proteins involved in blood coagulation, fibrin clot formation, and platelet exocytosis. Conversely, these proteins can be associated with disease severity and mortality risk and can serve as biomarkers for a better prognosis.

Consistent with previous studies, multiple acute phase proteins (APPs) like APCS, C4B, A2M, SERPING1, SERPINA3, and FGG were upregulated in severe patients.^{41,66} APPs are manifested as the body's innate response to any kind of stress. Tissue damage caused by injury or infection instigates a local inflammatory response that leads to the release of pro-inflammatory cytokines. APPs are synthesized and released mainly by liver hepatocytes in response to these cytokines.⁶⁷ Severe COVID-19 patients tend to have higher levels of pro-inflammatory cytokines⁶⁸⁻⁷⁰, which explains the elevated APP levels and the acute inflammatory state correlating with disease severity. The complement system is a significant contributor to the acute phase response against infection. C4B is a proteolytic product of complement factor C4 and is involved in the propagation of all the three complement pathways;⁷¹ APCS or serum amyloid P component (SAP) is an activator of the classical pathway of the complement system.⁷² Other proteins involved in the complement system that were downregulated in the severe cohort include CFI, C8A, CFD, CFP. Complement factor I (CFI) down-regulates the complement system by inhibiting complement C3b and C4b⁷³, while complement factor D (CFD) and properdin (CFP) play an essential role in the initiation and propagation of the alternate pathway in complement activation.^{74,75} Complement activation is the first line of defense against invading pathogens. However, unrestrained and prolonged complement activation can lead to fatal consequences associated with most of the severe COVID-19 cases.⁷⁶⁻⁷⁸ This disrupted fine-tune between the regulatory complement proteins is consistent with the prolonged systemic complement activation observed in severe patients.

Multiple antiviral drug therapies, as well as clinical drug trials, are going on to come up with a definitive solution for this life-threatening viral infection. Current approaches of treating various stages of COVID-19 patients with commercially available drugs include two major categories; treatment with antiviral drugs

and immune modulators. HIV protease inhibitors are quite famous as they belong to the former category, but still, no definitive studies have proven those drugs to be potent inhibitors; hence the quest has to be continued.⁷⁹ In our study, we performed in silico drug re-purposing analysis with 9 proteins from our proteomic analysis against a library of 58 small molecules. The chosen drugs are previously found to target the protein-protein interactions happening between SARS-CoV-2 and human proteins in a cell line model.⁸⁰ Two FDA-approved drugs, Selinexor and Ponatinib, were found to inhibit most of the proteins belonging to two different cohorts; COVID-19 positive vs. COVID-19 negative and non-severe Vs. Severe patients' plasma. Previously, Food and drug administration (FDA) had approved Selinexor for the treatment of multiple myeloma in combination with Dexamethasone.⁸¹ The drug is a first-class exportin-1 (XPO1) inhibitor that brings apoptosis in cancer cells by blocking nucleocytoplasmic transport of tumor suppressor proteins.⁸² Although developed originally as anticancer-drugs, Exportin inhibitors can act as antiviral drugs as they have the potential to block the intracellular replication of viral particles by inhibiting the transport of viral replication proteins into the cytoplasm.⁸³ Hence, the drug is currently under phase 2 clinical trial for COVID-19 infection (ClinicalTrials.gov Identifier: NCT04349098). Five plasma proteins from our study, including Thyroxine-binding globulin (SERPIN A7) and Heparin cofactor 2 (SERPIND1) belonging to the family of serine protease inhibitors (SERPINs) shown to interact tightly with Selinexor, suggesting these SERPINs could be a target for the drug. Both proteins are also seen to interact with another FDA-approved drug called ponatinib. Originally a tyrosine kinase inhibitor, Ponatinib is used to treat patients with chronic myeloid leukemia (CML).⁸⁴ It is currently under no clinical trial for COVID-19 patients but, recent studies in mice models showed it could suppress the cytokine storms from viral infections like influenza.⁸⁵ Hence ponatinib, as an immune modulator, appears to be a suitable drug for making therapeutic cocktails against COVID-19 infection in the future.

A stitch in time saves nine. Perhaps no proverb holds true as this when it comes to managing the case fatality in COVID-19. While the COVID-19 pandemic has unleashed an unprecedented crisis on most lives and livelihood, it is the health workers who have borne the brunt of the pandemic. With limited availability of hospital infrastructure and overworked staff, it was pertinent to uncover factors leading to the severity of symptoms associated with COVID-19 to reduce the caseload in hospitals and manage severe cases at an accelerated pace. Further, the validation of these biomarkers can help clinicians in faster disease prognosis and better survival rates, especially in the vulnerable population, while selecting drugs based on the severity of infection would help better manage symptoms.

Declarations

Data availability

All proteomics data associated with this study are present in the manuscript or the Supplementary Materials. Raw MS data and search output files for proteomics datasets are deposited to the ProteomeXchange Consortium via the PRIDE partner repository with the dataset identifier PXD022296 (Link: <https://www.ebi.ac.uk/pride/archive/login>, Username: reviewer_pxd022296@ebi.ac.uk, Password:

Ewqtl0NJ). Targeted proteomic data is deposited on Panorama Public, and the ProteomeXchange ID reserved for the data is PXD022475. It can be accessed using the access URL- https://panoramaweb.org/COVID_PLASMA.url

Acknowledgments

The active support from Prof. Ambarish Kunwar from the Department of Biosciences & Bioengineering to fabricate UV transport device for sample transport and biosafety aspects is gratefully acknowledged. We are also grateful to Dr. Jaishree Garhyan, JNU, New Delhi, for discussion on biosafety guidelines. The authors thank Kasturba Hospital for Infectious Diseases for sample collection and sharing sample related information. The study was supported through Science and Engineering Research Board (SERB), the Government of India (SB/S1/COVID-2/2020), and a seed grant from IRCC, IIT Bombay to SS. MASSFIIT (Mass Spectrometry Facility, IIT Bombay) from the Department of Biotechnology (BT/PR13114/INF/22/206/2015) is gratefully acknowledged for MS-based proteomics work. The authors also wish to thank the PRIDE team for helping with the mass spectrometric data downloading and deposit in ProteomeXChange/PRIDE.

Author's Contributions

Concept and design of the study were carried out by S.S., J.S, O.S. Sample collection was done by S.A., R.B, V.P, A.S. and sample preparation was done by K.S., M.C, S.Gh, R.B, A.B. Mass Spectrometry analysis, and method optimization was done by A.B, S.G, S.S. MRM (Multiple reaction monitoring) was done by S.G, S.S, M.G.J.P, J.R, A.S. Statistical Data Analysis, and Data Visualization was done by D.B, A.S, A.V, A.A., K.S., S.S. Docking study was performed by A.B, A.S, A.M, K.M. Manuscript writing and Review by S.S, K.S, A.A, M.C, A.B, S.G, R.B, D.B, A.V, A.S, and A.M.

Declaration of interests

The authors declare no competing interests.

Figures

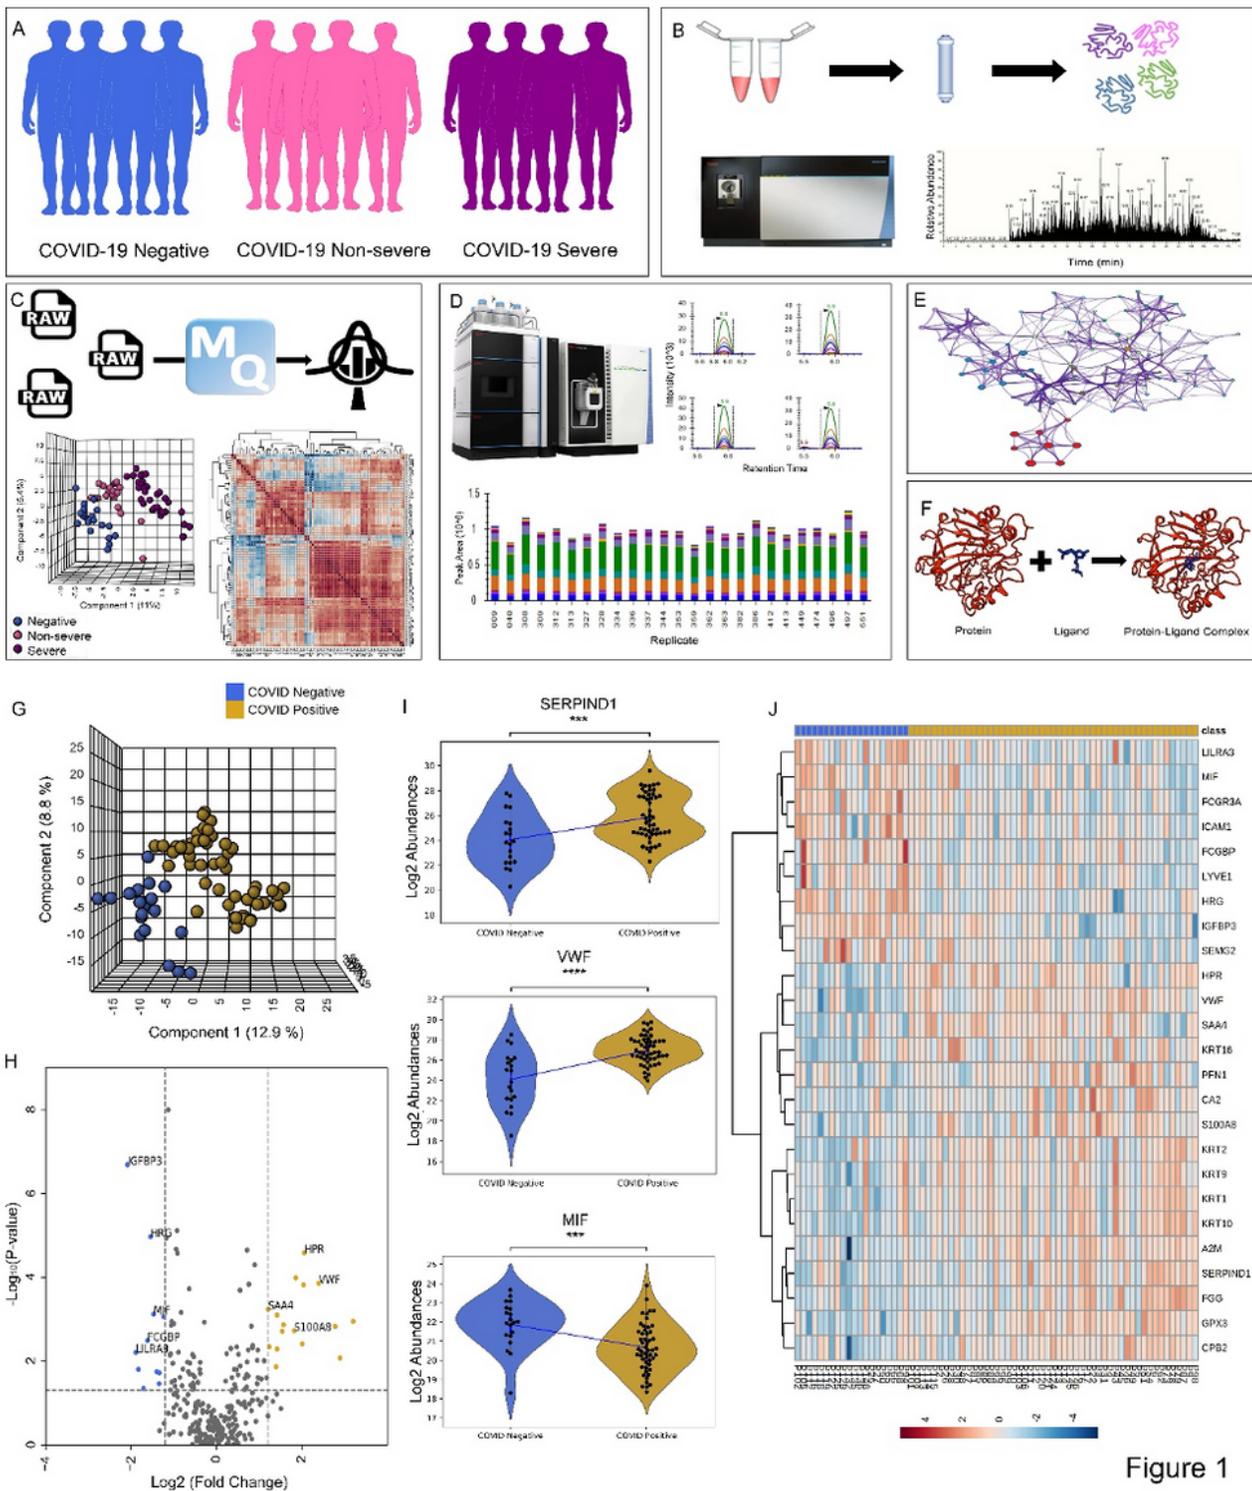

Figure 1

Figure 1

Landscape of Proteomic analysis of COVID-19 positive patients: Figure 1A represents the sample cohort which includes 20 COVID-19 Negative, 18 COVID-19 Non-Severe and 33 COVID-19 Severe patients; Figure 1B depicts the schematic workflow of Label-free quantification under discovery proteomics; Figure 1C

illustrates the overview of statistical data analysis; Figure 1D represents the use of synthetic peptide in Multiple Reaction Monitoring (MRM) under targeted proteomics, representative peaks are shown; Figure 1E and 1F represents the outline of biological network analysis and docking study respectively; Figure 1G represents the segregation between COVID-19 Positive (includes Severe and Non-Severe) and COVID-19 Negative samples; Figure 1H portrays a volcano plot showing significant differentially expressed protein; Figure 1I displays violin plot of SERPIND1, VWF and MIF protein (ns: $5.00e-02 < p \leq 1.00e+00$; : $1.00e-02 < p \leq 5.00e-02$; *: $1.00e-03 < p \leq 1.00e-02$; *: $1.00e-04 < p \leq 1.00e-03$; **: $p \leq 1.00e-04$) and Figure 1J depicts validation of acute phase proteins like SAA1 and SAA2 in different study cohorts.

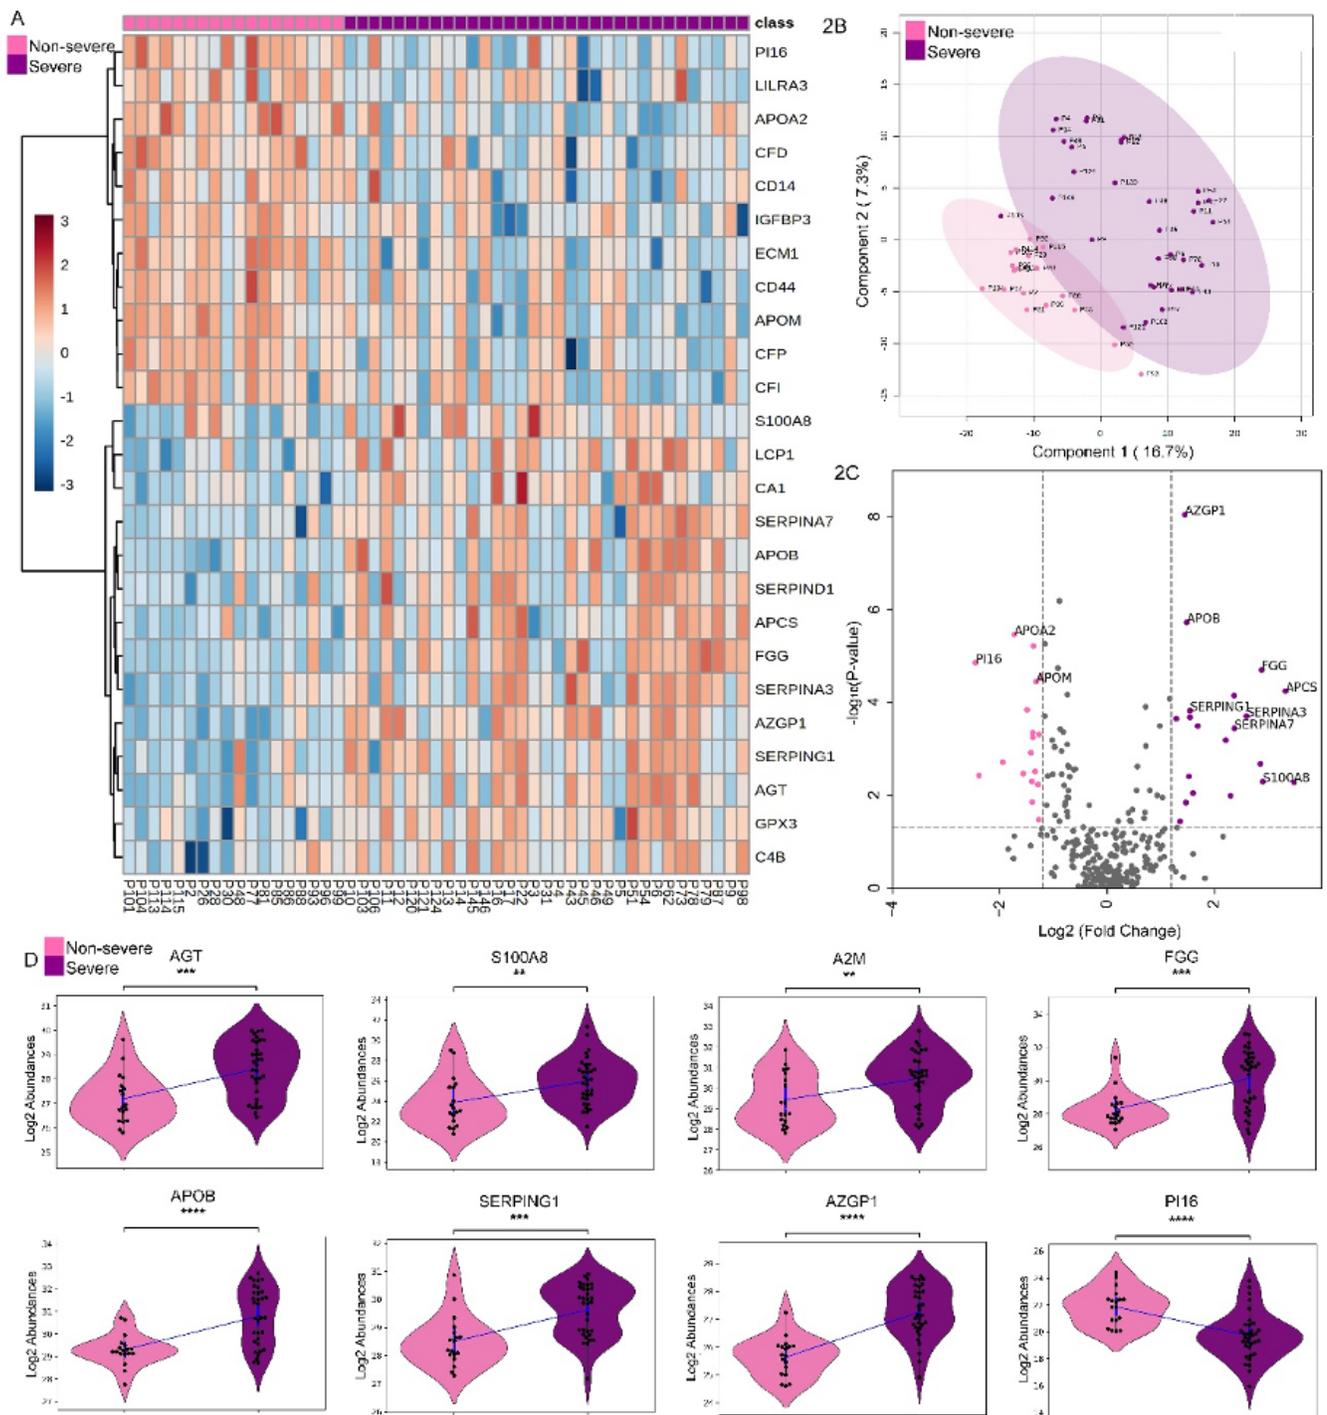

Figure 2

Figure 2

Proteomic analysis of COVID-19 Non-Severe and COVID-19 Severe patients: Figure 2A represent top 25 differentially expressed of Severe and Non-Severe in the form of Heatmap; Figure 2B and 2C depicts the PLSDA clustering and significant DEPs in the form of Volcano plot respectively; Figure 2D display a panel of 8 protein found to be most relevant in terms Severe vs Non-severe (ns: $5.00e-02 < p \leq 1.00e+00$; $1.00e-02 < p \leq 5.00e-02$; *: $1.00e-03 < p \leq 1.00e-02$; **: $1.00e-04 < p \leq 1.00e-03$; **: $p \leq 1.00e-04$).

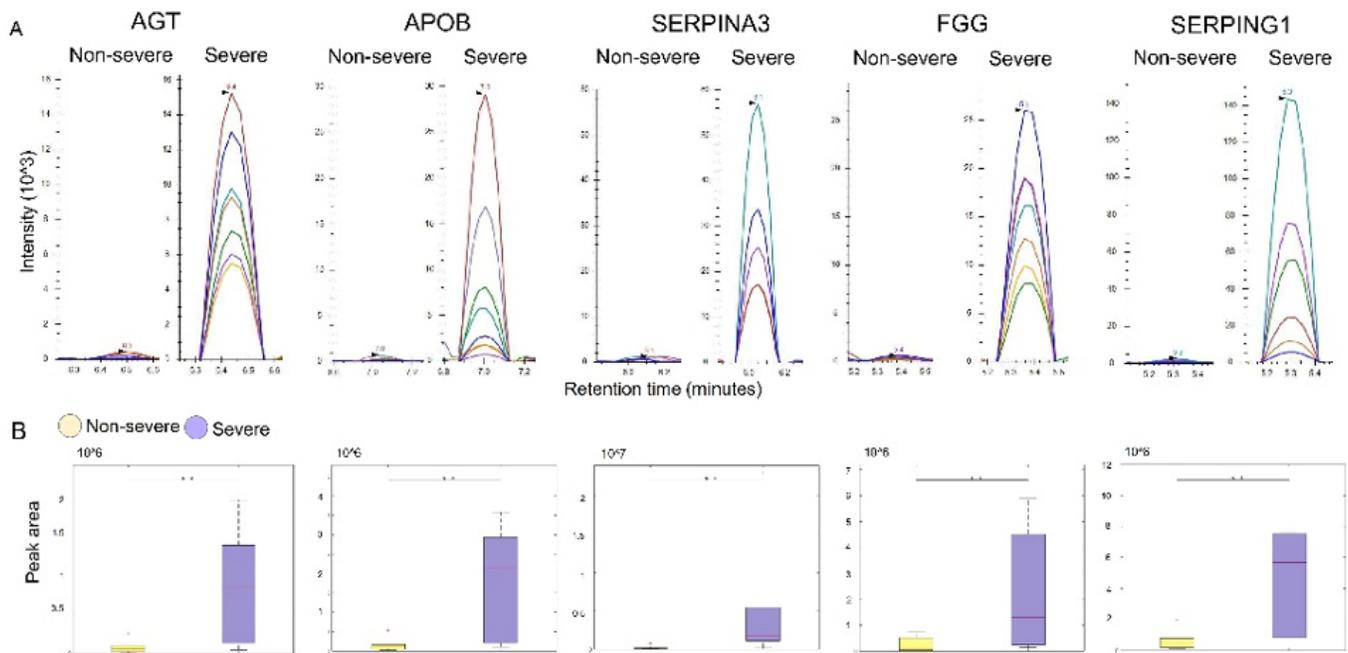

Figure 3

Figure 3

MRM analysis of proteins overexpressed in COVID-19 severe vs COVID-19 non-severe patient samples. A. Peak shapes (as seen in Skyline) of representative peptides of proteins AGT, APOB, SERPINA3, FGG, and SERPING1 respectively, and B. Box plots showing variation in terms of peak areas between severe vs non-severe samples for the same proteins.

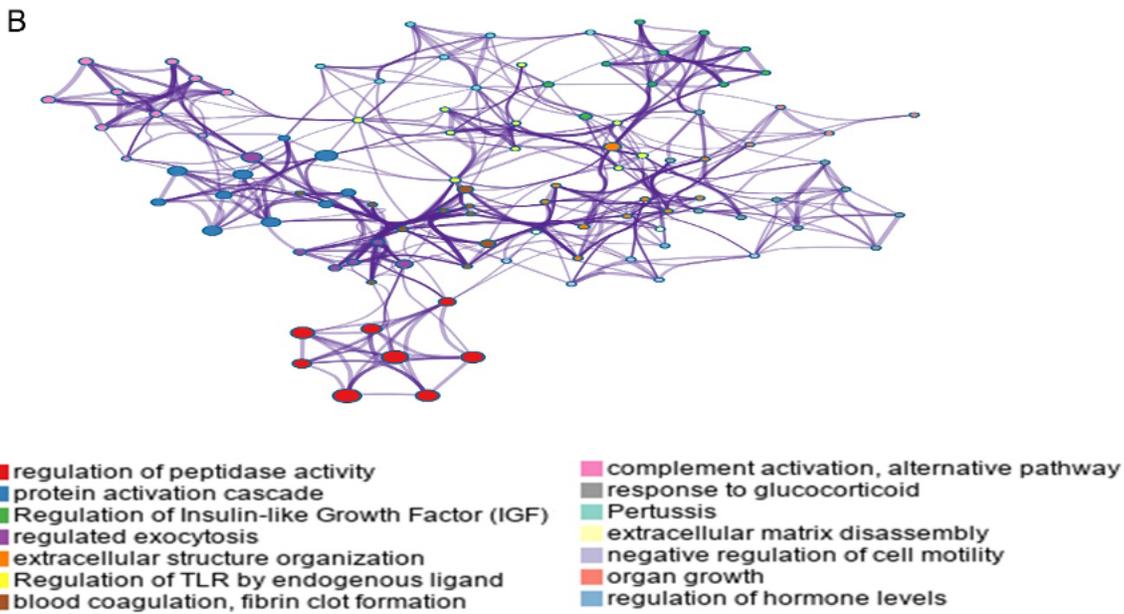

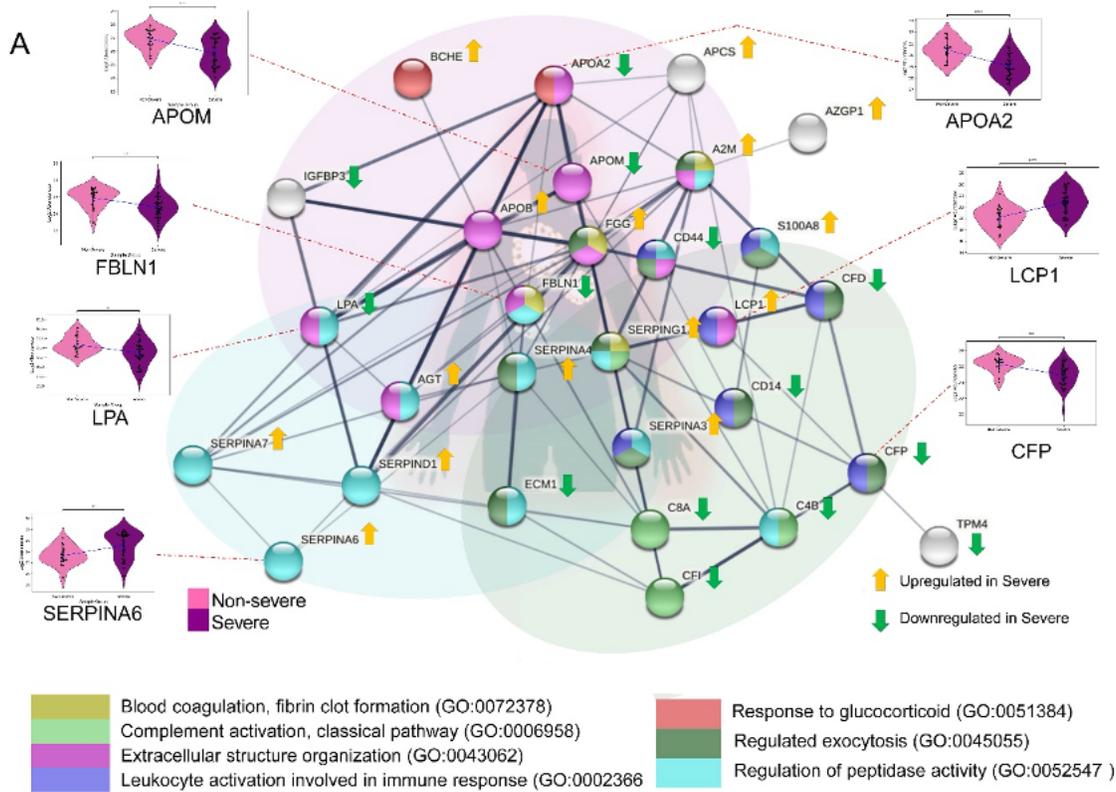

Figure 4

Biological Pathway and Network analysis of differentially expressed protein in Severe vs Non-severe comparison: Figure 4A represents the enriched biological processes with their co-expressed proteins in the form a bipartite network where few proteins has been shown in the form violin plot (ns: $5.00e-02 < p \leq 1.00e+00$; $1.00e-02 < p \leq 5.00e-02$; *: $1.00e-03 < p \leq 1.00e-02$; *: $1.00e-04 < p \leq 1.00e-03$; **: $p \leq 1.00e-04$). Figure 2B depicts bar graph of enriched gene ontology based on DEPs, where x axis represents

-log₁₀ p Value and y axis represents Gene Ontologies; Figure 4C shows network of enriched terms colored by clusters, where nodes that share the same clusters are typically close to each other.

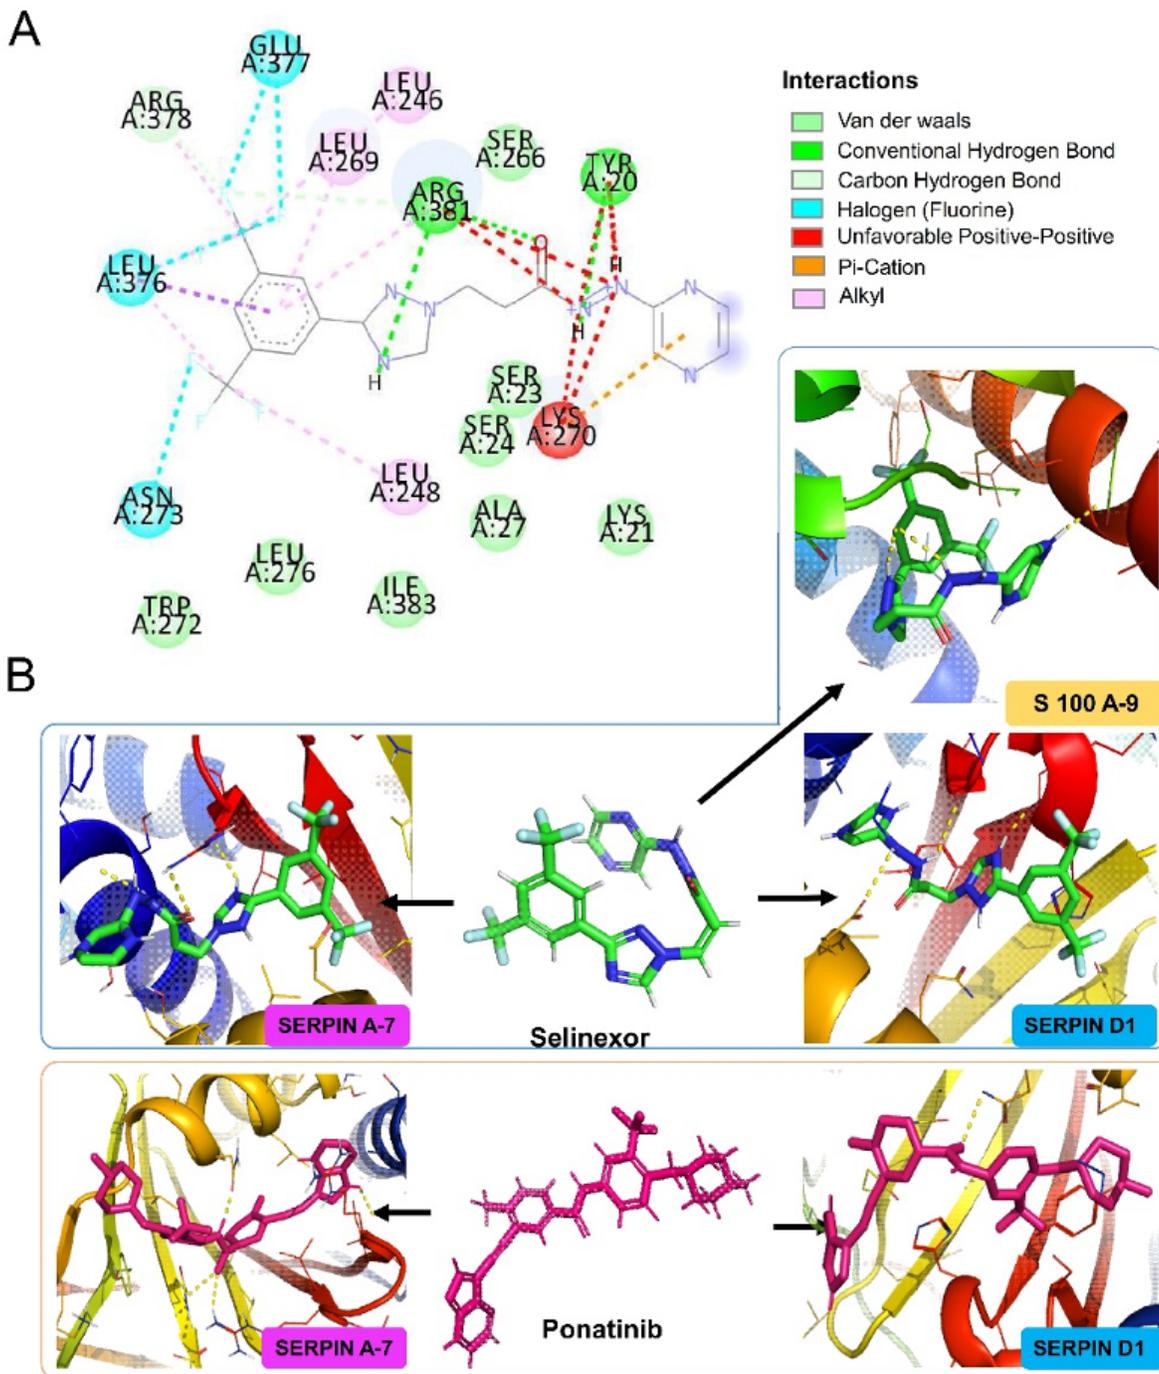

Figure – 5

Figure 5

In-silico molecular docking of drugs against upregulated proteins from different stages of COVID infection: Figure showing the docking results of three different target proteins with two FDA-approved drugs Selinexor and ponatinib. Figure 6A represents the predicted 2D interaction diagram of Selinexor

with SERPIN A7 involving various chemical bonds. Figure 6B shows the 3D diagrams which represent the binding pockets as well as the interaction of the drugs to three differentially expressed proteins, SERPIN A7, SERPIN D1, and S100 A9. Selinexor drug binds with SERPIN A7 with -9.3 Kcal/mol of binding affinity, SERPIN D1 with -8.7 Kcal/mol of binding affinity, and S100 A-9 with -7.5 Kcal/mol of binding affinity. Drug Ponatinib binds with SERPIN A7 with -9.3 Kcal/mol of binding affinity and with SERPIN D1 with -8.4 Kcal/mol binding affinity.
