Abstract

Background: This work summarizes the mortality cases of twenty-five free-ranging Eurasian wild brown bears (*Ursus arctos arctos*) from the Cantabrian mountain range submitted for necropsy in Asturias and Castilla y León (northwestern Spain) from '1998 to 2018'.

Results: Causes of death were classified both caused by (i) "human intervention" or "natural causes" and based on (ii) "infectious" or "non-infectious" etiology. In four cases (16%) it was not possible to determine the cause of death due to the inadequate preservation of collected specimens or insufficient tissue availability. Based on "human intervention" or "natural causes", seven out of the 21 (33.3%) brown bears in which the cause of death could be determined died as a consequence of "human intervention" due to illegal hunting (shooting or snare), handling or strychnine poisoning. In contrast, fourteen (66.7%) brown bears died by "natural causes" due to traumatic lesions (fights, unknown traumas or infanticide), infectious canine hepatitis, neoplasia, or mushroom poisoning. Based on "infectious" or "non-infectious" etiology nine out of the 21 (42.9%) brown bears died due to "infectious diseases", namely gangrenous myositis, infectious canine hepatitis or septicemia. The remaining twelve (57.1%) animals died due to "non-infectious" causes, which included handling, traumatic lesions such as shooting, snare, fighting or infanticide, strychnine poisoning, mushroom poisoning or neoplasia. In six of those cases traumatic lesions caused by human activities or by natural causes were complicated with bacterial infection (clostridiosis and septicemia) which finally caused the death of those animals. Additionally, exertional myopathy was observed in the handled animal and in one bear found in a snare.

Conclusions: In a non-hunted population of Eurasian brown bear from the Cantabrian mountain range, main cause of death is attributed to "natural causes" mostly due to traumatic lesions and infectious diseases (primary developed such as infectious canine hepatitis or secondary developed such as clostridiosis or septicemia) which is in contrast to previously reported data for other bear populations. These data are valuable and may help in the conservation and management of this recovering population.

Background

In Spain, the endangered Eurasian brown bear (*Ursus arctos arctos*) population is located in the Cantabrian mountain range (northwestern Iberian Peninsula) and represents the southwestern limit distribution for this species in Europe [1]. The population of free-ranging Eurasian brown bear has recovered during the last two decades (2000-2020) from approximately 100 individuals in the '1990s' to 230-260 presently [1, 2]. The deaths of brown bears in nature sometimes can be attributed to human interventions, i.e. shooting, poisoning or traffic accidents, and on other occasions death is due to natural causes, i.e. infanticide [3, 4].

The identification of causes of mortality in wild natural populations is relevant for the correct design of conservation strategies and management programs. However, knowledge on the mortality among bears is limited because of the difficulty in finding the dead animals in nature, and certain percentage of dead animals remains unrecorded.

The aim of the present work is to summarize the confirmed causes of deaths and most significant findings related to deaths reported in twenty-five free-ranging Eurasian brown bears submitted for necropsy in Asturias and Castilla y León (northwestern Spain) over the past 20 years. These data are valuable and may help in the conservation and management of this recovering population.

Results

Classification of causes of death

The cause of death and relevant pathological findings in the twenty-five brown bears studied is shown in Table 1 and Figure 1. In four (4/25, 16%) cases it was not possible to determine the cause of death due to inadequate preservation of collected specimens or insufficient tissue availability. The pathological findings on six animals revealed secondary bacterial infection followed by primary traumatic event caused either by human activities or natural causes. Three causes of death (*Clostridium sordellii* infection in one bear, infectious canine hepatitis caused by canine adenovirus type 1 (CAv-1) in three bears and cholangiocarcinoma in one bear) had been already described in previous papers by our group [5-7].

Mortality cases were classified both caused by (i) "human intervention" or "natural causes" and based on (ii) "infectious" or "non-infectious" etiology.

Based on caused by "human intervention" or "natural causes", seven out of the 21 (7/21, 33.3%) brown bears in which the cause of death could be determined died as a consequence of "human intervention" due to illegal hunting [wire snare hunting ($n=3$, 14.3%) and shooting $n=2$ (9.5%)], handling ($n=1$, 4.8%) and strychnine poisoning ($n=1$, 4.8%). In contrast, fourteen (14/21, 66.7%) brown bears died by "natural causes" due to traumatic lesions ($n=9$, 42.9%) [fights ($n=4$, 19%), unknown traumas ($n=3$, 14.3%) or infanticide ($n=2$, 9.5%)], infectious canine hepatitis ($n=3$, 14.3%), neoplasia ($n=1$, 4.8%) or mushroom poisoning ($n=1$, 4.8%).

Mortality data was also stratified based on "infectious" or "non-infectious" etiology. Nine out of the 21 (9/21, 42.9%) brown bears died due to "infectious" diseases, namely gangrenous myositis ($n=5$, 23.8%; four of which were proven to be from clostridiosis), infectious canine hepatitis ($n=3$, 14.3%) or septicemia ($n=1$, 4.8%). The remaining twelve (12/21, 57.1%) animals died due to "non-infectious" causes, which included handling ($n=1$, 4.8%), traumatic lesions ($n=8$, 38.1%) such as shooting, snare, fighting or infanticide, strychnine poisoning ($n=1$, 4.8%), mushroom poisoning ($n=1$, 4.8%) or neoplasia ($n=1$, 4.8%). Additionally, the pathological findings on six animals revealed secondary bacterial infection followed by primary traumatic event caused either by human activities (i.e. wire snare hunting) or natural causes (i.e. fights) (Figure 1). Exertional myopathy was observed in two bears, a handled animal and in one bear found in a snare.

Description of causes of death

Cases of death caused by traumas such as shooting (metallic fragments were found), wire snares, fighting or infanticide were easier to determine not only based on necropsy and histopathological studies but also using complementary diagnostic techniques (i.e. radiography) or knowledge of the behavior of this species. *Ante mortem* traumatic lesions always showed vascular reactions such as hemorrhages, hyperemia, congestion or edema. In fighting and infanticide cases lesions in skin, muscles or bones showed signs compatible with bites and scratches. In two animals the origin of traumas could not be determined. Other causes were more difficult to discern and are reported below.

Infectious diseases

The five bears (bears number 1, 8, 10, 15 and 23) with secondary gangrenous myositis (Table 1, Figure 1), as a consequence of wire snare hunting, infanticide, fights or traumas, showed serohemorrhagic edema in the abdominal cavity, thorax, pericardium, and skeletal muscle, and hemorrhages in heart, skeletal muscles, stomach, intestine, liver, spleen, and kidney. The case description of bear 8 was previously reported [5]. Microscopically, vascular damage and hyperacute myodegeneration consisted of myonecrosis, edema, gas, extravasation of fibrin into the interstitial spaces, and lacunar dissolution of myofibers in skeletal muscles were observed using hematoxylin-eosin and Masson's trichrome stains. *Clostridium sordellii* was identified by Gram stain and culture [5] as the etiological agent of the lesions in four brown bears. In two of these four bears each, the *C. bifermentans* and *C. septicum* were also isolated. The presence of *C. sordellii* was always associated with previous muscle damage (i.e. traumas) that triggered its proliferation. In bear number 15 *Clostridium* spp could not be isolated. An additional bear (number 12) showed septicemia secondary to fighting although the etiological agent could not be determined.

Gross lesions in the three bears (bears number 11, 14 and 20) with infectious canine hepatitis caused by CAdV-1 was previously described [6] and consisted of congestion and hemorrhages in several organs; hemorrhagic fluid in thoracic and abdominal cavities; friable and yellow-tinged liver; hepatomegaly; thickening of the gall bladder due to edema [6]. Microscopically the main pathological findings appeared in liver and gall bladder. The liver showed mild centrolobular multifocal degeneration and necrosis of hepatocytes, with the presence of intranuclear inclusions bodies and low inflammatory infiltration mainly of lymphocytes. The gall bladder showed edema of the wall. Additionally, non-purulent encephalitis was observed. CAdV-1 was confirmed by quantitative polymerase chain reaction (qPCR) and immunohistochemistry [6].

Exertional (degenerative) myopathy

In two animals exertional myopathy was diagnosed. One bear (bear number 1) additionally exhibited signs of clostridiosis after being captured in a snare and died after one week. A female cub also died due to exertional myopathy after handling (bear number 9). The cub was found alone in the wild when it was two months old and it was kept in captivity until it was nine months old. The cub died during transit in an attempt to reintroduce it back into the wild. Both animals showed gross lesions consisting of dry and pale cardiac and some skeletal (mainly intercostals and femoral) muscles (Figures 2a and 2b). Microscopically severe segmental degeneration of muscles was observed and consisted of hypercontracted fibers, extensive Zenker's hyaline degeneration and coagulative necrosis of myofibers (Figures 2c to 2h). Bear number 1 also showed an intensive infiltrate mainly consisting of lymphocytes and macrophages, as well as mineralization in the affected muscles (Figure 2f). In that animal necrotic myofibers with surviving satellite cells, invading macrophages and elongating myoblasts, all indicative of events of regeneration, were also observed (Figure 2d). The cub also showed hypoplasia of adrenal glands (1.7 grams, 0.004% relative weight; physiological relative weight 0.03% [8]).

Strychnine poisoning

In the bear affected by strychnine poisoning (bear number 6) extensive hemorrhages were found in several organs (heart, lungs, liver, kidney, spleen, stomach and intestine) often showing hemothorax, hemopericardium and hemoperitoneum. Microscopically vascular damage and diffuse necrosis in those organs were the most common findings. Strychnine was identified by chromatography from hair samples in a private company.

Neoplasia

Cholangiocarcinoma was observed in the liver of an old female (bear number 13). A complete description of this case was already published [7]. Briefly, microscopically liver tumor tissue showed tubular, acinar or pseudoglandular structures in the area facing a large cavity of necrosis with a thick trabecular growth pattern. Multiple small nodules were also present in the gall bladder. Metastatic encapsulated foci of cholangiocarcinoma were located in lung parenchyma, adrenal glands and articulation of the left elbow.

Mushroom poisoning

Bear number 19 showed hemorrhagic gastritis and diffuse hepatic and renal necrosis compatible with mushroom poisoning, likely due to ingestion of poisonous *Amanita* spp, although that could not be confirmed by toxicological analysis.

Discussion

This study shows that the main causes of deaths in Eurasian brown bears from the Cantabrian mountain range are those caused by infectious diseases (42.9%), mainly by clostridiosis (associated to previous muscle damage) or infectious canine hepatitis. As an example, in Sweden, where ninety-eight animals were analyzed, no deaths of brown bears were attributed to any infectious disease [4]. Thus, the confirmation of *C. sordellii* secondary to traumas and CAHV-1 (the agent of infectious canine hepatitis in dogs) as relevant causes of death in Eurasian brown bear is probably the most outstanding finding in this study. In contrast with previous data on brown bears, for the first time infectious diseases are described as an important cause of death. The four fatal cases of clostridial infection described to date, compared to the few descriptions reported worldwide, could show a higher susceptibility of the Cantabrian brown bear population to these bacteria [5]. Gross lesions such as hemorrhages and edema in skeletal muscle and internal organs might lead to suspect of clostridial infection in bears found dead in the nature. The putative high susceptibility to infectious pathogens reported here might be a consequence of a weaker immune system due to the lower

genetic diversity described for this species in the Cantabrian range subpopulation [9, 10]. Another possibility might be a high degree of circulation of the pathogens both in the environment and sympatric species (i.e. CAdV-1 carriers such as wolves or not sanitarily controlled dogs in rural areas) [6].

Two animals died showing exertional myopathy as a consequence of extreme exertion and stress after trapping by a snare [11] or handling. Those are to our knowledge the second and third cases of death by exertional myopathy reported in bears in the literature worldwide. The first case was described by Cattet et al. (2008) in a grizzly bear that died approximately 10 days after capture by leghold snare in Canada [12]. Those three cases confirm the fact that the prolonged suffering in bears might cause exertional myopathy as occurs in other mammal species, i.e. red fox or cervids [13, 14]. Therefore that should be taken into account in the management of bears, especially when capturing and handling free-living specimens, trying to minimize stress as much as possible. Some measures to reduce stress and complications due to capture myopathy might include minimize noise and activity, limit captures to periods with reduced temperature or provide sodium bicarbonate, Selenium or Vitamin E supplements [14]. The acute presentation of adrenal hypoplasia shown in the cub could be precipitated by the physiologic stress suffered [15].

Despite of the limited number of studied cases (related to the conservation status and behaviour of the species that hampers the detection of moribund or dead bears in nature) the data reported in the present work confirm the persistence and relevance of causes of death directly related to human intervention (33%). The total number of mortalities and causes of death are a conservative figure as unreported mortality is difficult to estimate. In this sense small carcasses from cubs or yearlings are even more difficult to find, therefore this study might be also limited due to the biased sampling. Additionally the impossibility of establishing the cause of death in four brown bears submitted for necropsy due to the nature and/or preservation status of available samples must be taken into account when considering the frequency and importance of the different causes of death reported in this paper.

Nevertheless, the confirmation of six out of 25 brown bears submitted to the laboratory for necropsy confirmed as death by shooting, snare and poisoning (four of them from 1998 to 2008 and two from 2008 onwards) seems to agree with the apparent reduction in illegal killing after the mid-'1990s' [1, 16], suggested as a key factor for the recovery undergone during last two decades [2]. The causes of death should be clearly differentiated in small and isolated populations like in Spain, Italy or France with causes of death in large and hunted populations like in Canada. Similarly to our study, in the Trentino region of Italy [17] and in the French Pyrenees [18] which are also small and isolated populations, the main cause of death is from natural causes. In contrary, in large and hunted populations the main cause of death is human mediated. In this regard human actions were responsible of most grizzly bear mortalities in Canada [3]. In Sweden, Mörner et al. (2005) found that human caused mortality stands for 64% of total submissions; meanwhile bears killed by other bears and infanticide were the most frequent natural cause of death (16%) [4]. Reljic et al. (2018) and Krofel et al. (2012) reported for hunted populations in Croatia and Slovenia, respectively, more than 90% human caused mortality, mostly hunting, traffic collisions and intervention removals [19, 20].

The detection of four male bears that died after fighting, three due to traumas, three bears that died due to CAdV-1 infection, two cubs that died due to infanticide, one female died due to a cholangiocarcinoma and one male due to mushroom poisoning confirm the existence of deaths attributable to " non-human mediated" natural causes (67%) usually difficult to detect in nature, and thus highlight the importance of necropsies.

Traffic induced bear mortality has been documented as a common cause of death in bears in other European countries [4, 19-26]. In our study we have not reported any road-killed animals, despite one bear that died in a traffic accident (the only one reported in Spain to date) in León in 2008, although necropsy of this bear was not performed, and it is not included in this report [27].

Regarding the limited genetic variability of the Cantabrian brown bear population [2], and taking into account that a free-ranging bear can live about 25 years [2, 16], we can consider that the three animals found dead at the age of 19-20 years have had the opportunity to widely contribute to the genetic stock of the Cantabrian brown bear population. However, two out of the five necropsied cubs (40%) died due to CAdV-1 infection. Thus, we can consider that an important percentage of future progenitors might die due to that infectious disease among others causes, which can be important for the maintenance of genetic variability of the species, even more in this endangered population.

Conclusion

In summary the data in the present work represent a first review of the death causes reported at necropsy in the Cantabrian brown bear population since 1998. The apparent moderate but steady recovery experienced during last decades provides a new landscape for this endangered population, where recovery and conservation works will have to be accompanied by an increasingly important effort on surveillance and management programs of the species, focused on the control of infectious diseases shared between domestic and wild animals under the one health strategy.

Methods

Twenty-five free-ranging Eurasian brown bears, nine from Castilla y León and 16 from Asturias, of different sexes and ages (see Table 1) were necropsied from “1998 to 2018”.

After the detection of one dead animal and the exhaustive examination of the area in the field where the bear was found, a complete *post mortem* examination of each carcass was conducted at the University of León or Servicio Regional de Investigación y Desarrollo Agroalimentario (SERIDA, Asturias). Tissue samples were taken for evaluation using standard methods in microbiology [5], molecular techniques [6], virology [6], parasitology (coprologic study), toxicology and histopathology [5-7]. Histological stains included hematoxylin-eosin, Gram, Ziehl-Neelsen, Von-Kossa, Mallory Azan, Klüber-Barrera and Masson’s trichrome. A dental histological study [24] was performed when possible in order to determine the age of the bears. Data on bears carcass sites, necropsy findings and laboratory results were considered in making conclusions about the cause of death and allowed tracking of changes and trends in mortality throughout the years.

Declarations

Ethics approval and consent to participate

We comply with the IUCN Policy Statement on Research Involving Species at Risk of Extinction and the Convention on the Trade in Endangered Species of Wild Fauna and Flora. We also comply national and regional legislation on sampling of Cantabrian brown bear (Consejería de Fomento, Government of Principality of Asturias and Consejería de Fomento y Medio Ambiente, Junta de Castilla y León). Ethics approval was deemed unnecessary according to Spanish national regulations (Real Decreto 53/2013).

Consent for publication

Not applicable.

Availability of data and materials

The datasets used and/or analysed during the current study are available from the corresponding author on reasonable request.

Competing interests

The authors declare that they have no competing interests.

Funding

Techniques performed were supported by a grant from the Principado de Asturias, PCTI 2018–220 (GRUPIN: IDI2018-000237 and FEDER).

Authors’ contributions

AB and JFGM developed the concept of the study and collected all required data; AB, LJR, EG, RB, OA and JFGM collected and processed the samples, and analyzed and interpreted the data. AB and JFGM drafted the manuscript. All authors read and approved the final manuscript.

Acknowledgments

Authors thank colleagues from SERIDA, University of León, Servicios del Principado de Asturias (SERPA), Servicio de Espacios Protegidos y Conservación de la Naturaleza, Dirección General de Biodiversidad from Viceconsejería de Medio Ambiente del Principado de Asturias and Consejería de Fomento y Medio Ambiente de la Junta de Castilla y León for the invaluable collaboration. We thank Dr. Kevin P. Dalton for critically reviewing the manuscript.

7	14/06/2008	1 year	Male	Infanticide
8	27/08/2012	Adult	Male	Snare/gangrenous myositis (<i>Clostridium sordellii</i>)*
9	29/10/2012	Cub (9 months)	Female	Died after handling and transport/exertional myopathy
10	12/06/2014	3 years	Male	Fighting/gangrenous myositis (<i>Clostridium sordellii</i> and <i>C. septicum</i>)
11	15/06/2014	5 years	Male	Infectious disease: CAAdV-1**
12	12/12/2014	9 years	Male	Fighting/septicemia
13	29/04/2015	20 years	Female	Neoplasia: cholangiocarcinoma***
14	23/05/2015	Cub (4 months)	Male	Infectious disease: CAAdV-1**
15	16/10/2015	Adult	Male	Traumatic lesions/gangrenous myositis
16	05/03/2016	Adult	Male	Traumatic lesions due to fall
17	08/10/2016	Subadult	Male	Shooting
18	27/11/2016	6 years	Female	Snare/strangled
19	07/01/2017	6 years	Male	Mushroom poisoning; hepatic an renal necrosis
20	03/04/2017	Cub (3 months)	Female	Infectious disease: CAAdV-1**
21	21/04/2017	19 years	Male	Fighting and cliff fall
22	21/04/2017	20 years	Male	Fighting and cliff fall
23	29/09/2018	4 years	Female	Traumatic lesions/gangrenous myositis (<i>Clostridium sordellii</i>)
24	27/10/2018	5 years	N.d.	N.d.
25	08/11/2018	7 years	Male	N.d.

* [5]. ** [6]. *** [7]. Grey shadow: deaths by human intervention. N.d.: not determined. CAAdV-1: Canine adenovirus type 1. Bears 5, 7, 9, 11, 12, 15, 18, 24 and 25 are from Castilla y León. The remaining bears are from Asturias.

Figures

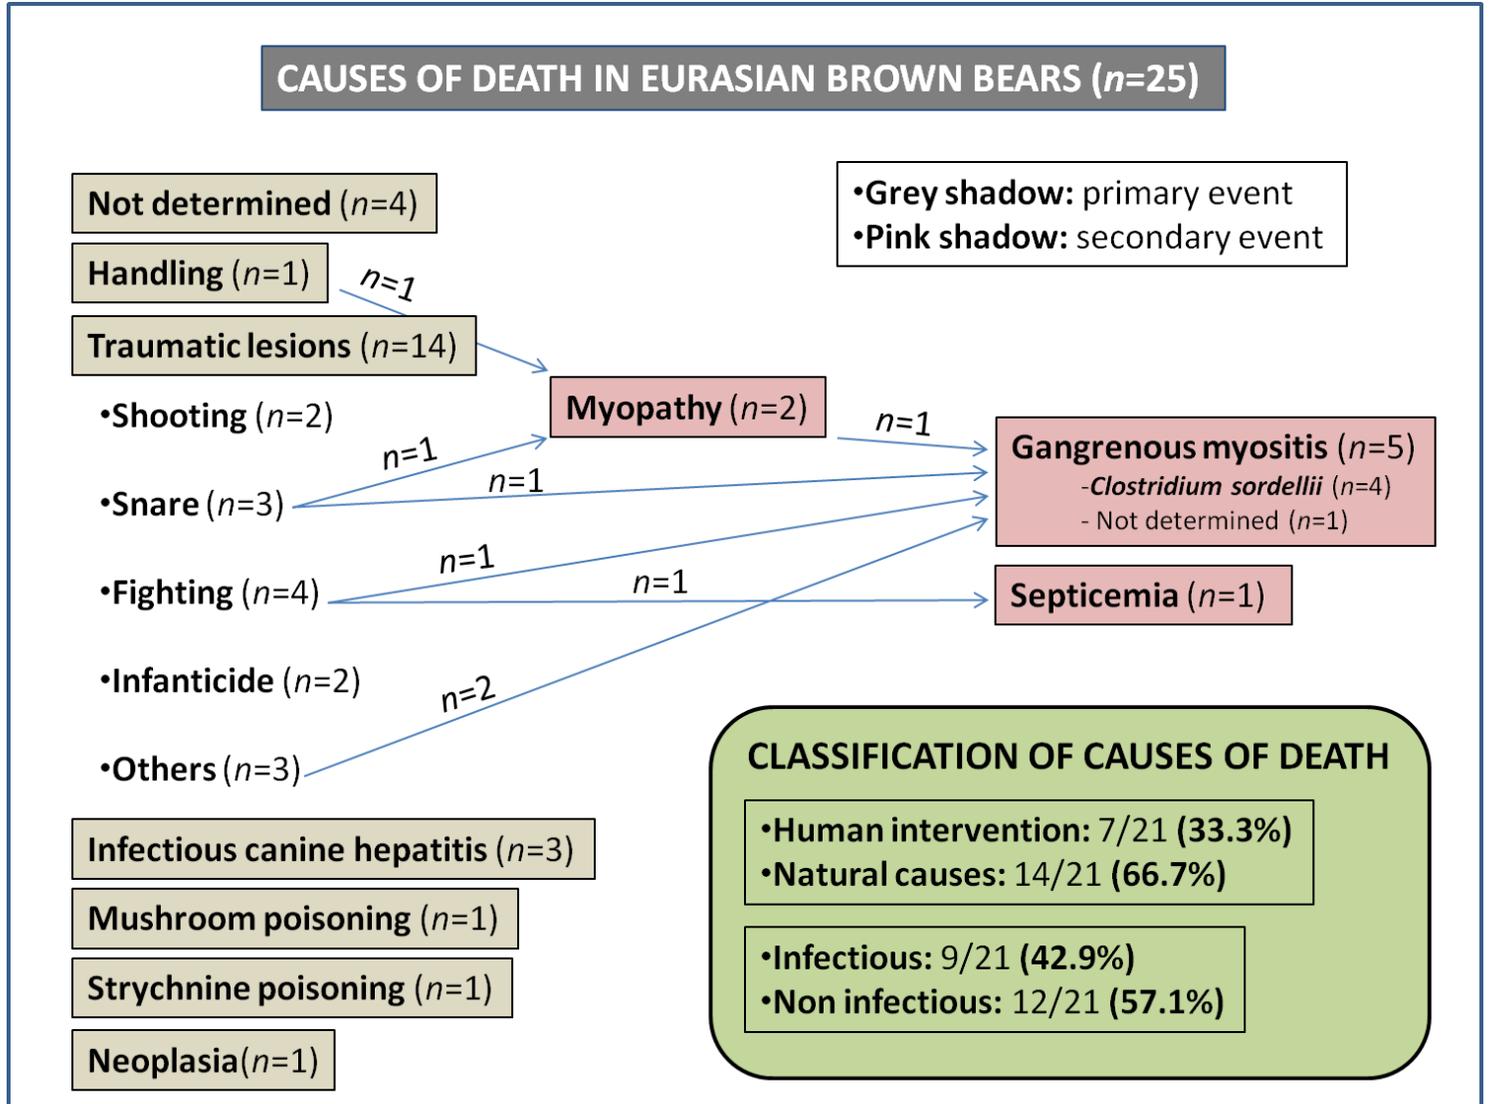

Figure 1

Mortality cases in Eurasian brown bears (*Ursus arctos arctos*) in Asturias and Castilla y León (northwestern Spain) from '1998 to 2018'. Blue arrows indicate bears which died from a combination of human activities or natural trauma and secondary bacterial infection.

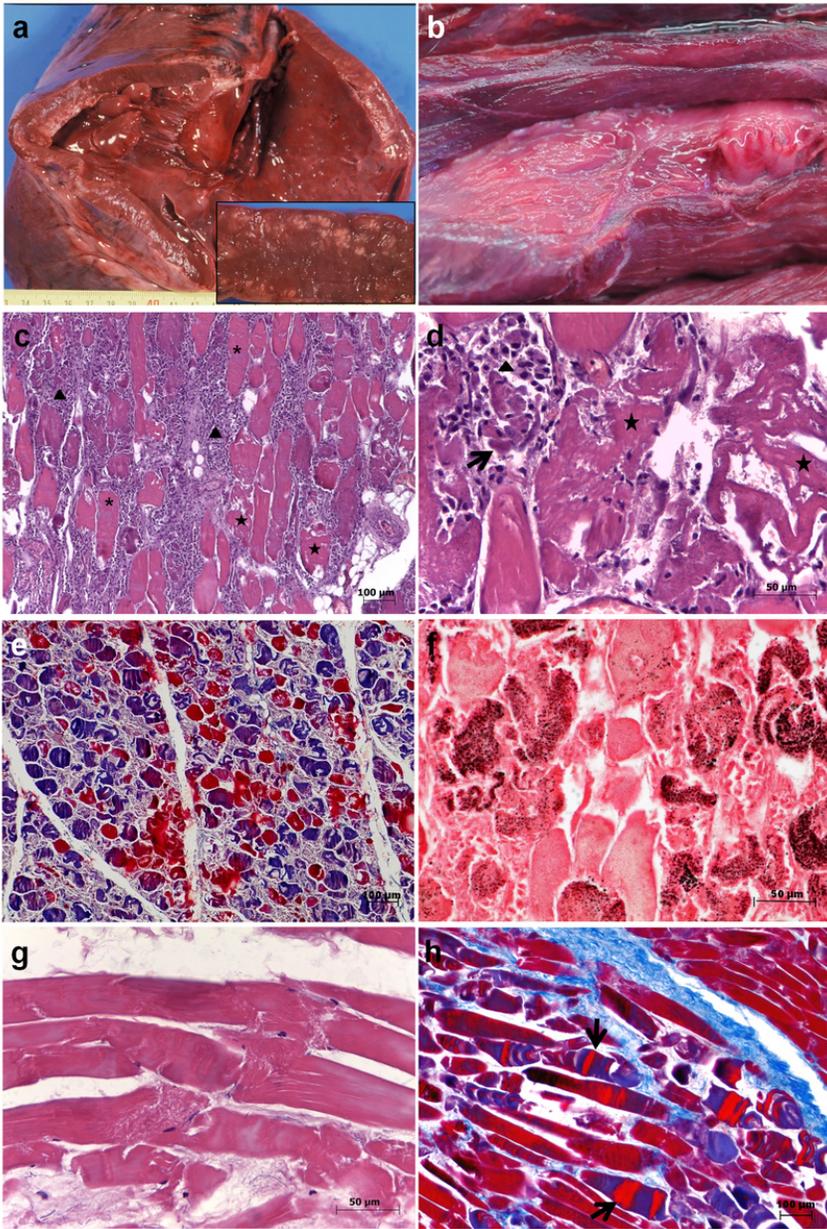

Figure 2

Severe exertional myopathy in Eurasian brown bears is shown. Figures a, c, d, e and f correspond to bear number 1 and Figures b, g and h to bear number 9 (see Table 1 for details). a) Gross lesions consisted of dry and pale cardiac muscle. Inset: detail of lesions in myocardium. b) Gross lesions consisted of pale skeletal (femoral) muscle. c) Extensive segmental hyaline degeneration in femoral muscle. Hypercontracted fibers (asterisks), coagulative necrosis and areas of myofibrillar lysis (stars), as well as intensive infiltrate mainly consisted of lymphocytes and macrophages (arrowheads). Hematoxylin-eosin staining. d) Detail of necrotic myofibers (stars) with surviving satellite cells (arrow), invading macrophages (arrowhead) and elongating myoblasts (asterisks) indicative of events of regeneration. Hematoxylin-eosin staining. e) Necrotic and lysed myofibers. Mallory Azan staining. f) Calcification (mineralization), hyalinization and necrosis of muscle fibers. Von Kossa staining. g) Segmental degeneration in a longitudinal section of intercostal muscle. In this case infiltrate is not present. Hematoxylin-eosin staining. h) Necrotic and hypercontracted (arrows) myofibers. Mallory Azan staining.
