**Version of Record:** A version of this preprint was published at BMC Musculoskeletal Disorders on April 21st, 2020. See the published version at <https://doi.org/10.1186/s12891-020-03244-y>.

## Abstract

**Background:** Prior studies have compared the posterior capsule repair group in primary total hip arthroplasty by posterior approach with the control group without posterior capsule repair, suggesting that the posterior capsule repair group had better clinical outcomes. However, it is still a controversy which treatment is more helpful for hip diseases. The purpose of our article is to obtain the postoperative outcomes between the 2 procedures. **Methods:** We performed a systematic search by browsing the MEDLINE, EMBASE, Cochrane Library. There is no restriction on the date of publication. Before we submit our manuscript, we have re-searched the literatures again, including the articles which directly compared the postoperative outcomes of the 2 procedures. **Results:** A total of 8 comparative studies were included in our meta-analysis. The posterior capsule repair group showed less dislocation rate, higher HHS, and even less postoperative Bleeding volume, however, there is no significant difference in ROM between the 2 groups. **Conclusion:** In conclusion, according to the current evidence, repairing posterior capsule during primary THA may have better functional outcomes, less dislocation incidence, and less loss of blood.

## Introduction

Total hip arthroplasty (THA) is a mature and beneficial orthopedic procedure for the treatment of diseases such as osteoarthritis. In the United States, there are more than 300,000 cases of hip fractures each year, and more than 200,000 cases of total hip replacement. And even millions of hip replacements are performed worldwide every year. It can alleviate the pain of patients and improve the function and limb deformity [1, 2]. Primary total hip arthroplasty with posterior approach has the advantages such as less soft tissue injury, shorter operation time, less bleeding volume and faster recovery. At present, Posterior approach for total hip arthroplasty is more commonly used than anterior approach.

However, the incidence of complications after posterior approach is higher than those after other approaches, especially early postoperative dislocation [3–5]. The complication of dislocation after posterior total hip arthroplasty (PTHA) is very common. Historically, it was reported that the dislocation rate was as high as 0.49–4.46% [6, 7].

Papadakis, S.A., et al suggested that the repair of posterior joint capsule during THA is beneficial to maintain biomechanical stability, promote early functional recovery and reduce the risk of dislocation [8]. Hummel, M.T., et al thought a larger diameter of the femoral head is beneficial to reduce the dislocation of the prosthesis after THA [9]. However, Pfirrmann, C.W., et al have found that even if the posterior joint capsule is strengthened during total hip arthroplasty, most of the posterior soft tissue is not enough to resist the tension of the repair site, which leads to the tear of the repair site [10]. Kao, J.T. and S.T. Woolson also reached a similar conclusion that joint capsule suture is of little significance due to its high failure rate, and there is no significant correlation between postoperative prosthesis dislocation and the role of posterior joint capsule. They believed that repairing the posterior joint capsule does not effectively reduce the risk of prosthesis dislocation after THA, but prolongs the operation time [9, 11].

Although the reconstruction of posterior articular capsule in total hip arthroplasty has been paid more and more attention in recent years, there is a lack of evidence-based medicine to show its superiority. At present, there is no consensus on whether the posterior capsule needs to be repaired during THA. Therefore, in this context, our specific purpose is to quantitatively evaluate whether posterior capsule repair affects the dislocation rate and reduces other complications.

## Methods

### Search Strategy

We strictly followed the PRISMA guideline to conduct this analysis [12] according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement. The literature searched for this study were begun after the predefined protocol for this review was registered with PROSPERO by all coauthors and the study protocol was published online at the PROSPERO International Prospective Register of Systematic Reviews. We systematically searched the electronic databases MEDLINE (through PubMed), EMBASE (through OvidSP), and CENTRAL (Cochrane Central Register of Controlled Trials, through the Cochrane Library) for relevant studies without language restrictions applied comparing the main fixation types. The literature search strategy for these 3 databases followed Medical Subject Headings combination with terms (Appendix 1).

### Inclusion and Exclusion Criteria

Two researchers (Xiaobo Sun and Xingyang Zhu) independently scanned the titles and abstracts of the literatures. After excluding the trials that obviously did not meet the inclusion criteria, they read the full text of the literatures that might meet the inclusion criteria to determine whether they met the inclusion criteria. Then cross-check, when the data is in doubt, we resolved it by a consensus or through discussion with the third researcher. We also investigated the reference list of each relevant study that were not identified by our original search and determined whether it would be included additionally. Data extraction included demographic data (age, sex, etc.) and available outcome indicators.

All randomized controlled trials (RCTs) and non-randomized controlled trials (nRCTs) directly comparing posterior capsule repair and posterior capsule without repair for patients with primary THA were identified and included from the search strategy. These studies should meet the following inclusion criteria: (1) THA procedure was performed for the first time; and (2) repair of posterior capsule was involved; and (3) the control group was unrepaired posterior capsule group (or capsulectomy group) in the original comparative study; and (4) posterolateral or posterior approach was used; and (5) at least one of the following indexes was reported: operation time, intraoperative bleeding, postoperative drainage, postoperative pain score, time of getting out of bed, postoperative dislocation rate, postoperative hip function Harris score and excellent and good rate evaluation. We also excluded studies that (1) revision of THA was performed; and (2) unclear or incomplete sample data were available; and (3) posterior capsule was not mentioned during procedure; and (4) anterior approach was used; and (5) postoperative effect was inaccurate.

# Study Quality Assessment

To assess the methodological quality, the nonrandomized studies were assessed using the nine-star Newcastle-Ottawa Scale (NOS), which is a validated tool suitable for assessing the quality of nonrandomised studies [13]. We used the Cochrane risk of bias tool to assess the risk of bias in the RCTs and determine whether biases might have affected the results [14]. Two researchers independently assessed the studies, and the disagreements between them were resolved through discussions with a third author or by consensus.

## Data Extraction

The data of all included studies were extracted by the first author according to a standardized data collection, then two other authors independently repeated the process and checked the data extracted by the first author. The data extraction form included the following topics: (1) research features (ie, authors, type of study, journal, year of publication, and country), (2) population information (ie, gender, body mass index [BMI], age, and Primary or non-primary THA), (3) intervention (ie, intraoperative repaired or unrepaired posterior capsule), and (4) outcome index (ie, postoperative dislocation, HHS score, etc.). If the study omits the necessary results, we would contact the authors by email or other means to obtain more data if necessary.

## Statistical Analysis

In each study, the odds ratio (OR) and relevant 95% confidence interval (CI) were commonly used as the measure of dichotomous variables such as postoperative dislocation rates. Given that the outcome is rare, reported OR was supposed to approximate RR (relative risk) on the basis of Cornfield's rare disease outcome assumption [15]. The mean difference (MD) or standard mean difference (SMD) was used for continuous variables such as HHS. We used statistical algorithms to estimate the standard deviation for those studies that provided only continuous variables for means and range [16]. Then we included studies where means and standard deviations are available.

The  $I^2$  and Q test were used to evaluate the heterogeneity among studies. The random effects model was in place of the fixed effects model for heterogeneity test, P values  $\leq .1$  or  $I^2 \geq 50\%$  [17].

Sensitivity analysis was used to assess the stability of the results (if necessary), and subgroup analysis was conducted to get more specific and detailed results if the data were available. Forest map was used to show the results of each individual study and associated pooled estimates of effect size. Funnel plots was conducted to judge whether there was publication bias for any of the studies. All statistical analyses were conducted using Review Manager (version 5.3.5 for Windows, the Cochrane Collaboration, the Nordic Cochrane Centre, Copenhagen, 2014).

## Results

### Study Selection

778 relevant citations were identified from three databases according to the literature search strategy described earlier. There were a total of 781 studies included, together with the three additional articles included in other publications. After deleting 105 duplicates, we obtained 676 articles. By reviewing titles and abstracts, 611 irrelevant clinical studies were excluded, and 65 clinical studies were remained. By reading the full-text articles, we excluded another 57 articles for the following reasons such as (systematic) reviews, surgery techniques, none-compare groups, cadaver researches, animal researches, TKA patients, no useful outcome data. The final 8 articles were deemed appropriate.

There was not combined effect size in one of these 8 studies which were selected. This article was given a descriptive analysis [18]. Finally, 7 publications from 1998 to 2010 were included in our meta-analysis [19–25]. 2 RCT studies were performed subgroups studies analysis [19, 25]. The detailed literature screening process is shown as PRISMA flow diagram in Fig. 1.

### Study Characteristics and Quality

Key characteristics of the included studies were provided in Table 1. From the 8 citations, 2 RCT [19, 25] studies and 6 nRCT [18, 20–24] studies were identified. 1,858 hips in the posterior capsule repair group were compared with 2,766 hips in the control group (without posterior capsule repair). All in all, the studies involved about 4624 primary THA cases (4523 patients). Seven studies [19–25] compared dislocation rates and 2 studies [19, 24] compared postoperative HHS between these two groups. Among the 8 studies, 2 studies were from USA [20, 23], 2 from Taiwan, China [19, 22], 1 from Mexico [21], 1 from Korea [24], 1 from Japan [18], 1 from Sweden [25].

The reported average follow-up for dislocation rates ranged from 6 months to 60 months. The maximum period was 60 months [19], and the minimum period was 6 months [23]. The time of dislocation ranged from at least 1 week to 6 months after surgery. Unfortunately, we did not find specific dislocation time in 4 studies. We contacted the authors, but failed. Mean age ranged from 51 [19] years to 69 (SD 8) [25] years. All the studies included were primary THA, and were divided into two groups. A 28-mm diameter femoral was used in 3 studies [21, 24, 25]. The study characteristics, clinical outcomes, and patient demographic details for the 8 studies are shown in Table 1. The methodological quality of involved studies ranged from seven to eight. Table 2 shows a moderate-serious risk bias of the included studies.

Methodological Assessment According to Six Domains of Potential Biases (Cochrane Risk of Bias Tool)										

## Postoperative dislocationrate

Seven studies [19–25] assessed the incidence of dislocation in a total of 4595 cases. We divided the studies into two subgroups (an RCT subgroup and an nRCT subgroup) for the subgroup analysis. 7 articles clearly reported the rate of postoperative dislocation after primary THA in the literature. heterogeneity test ( $I^2 = 0\%$ ) indicated that there is statistical homogeneity among the studies, so the fixed effect model was used to analyze. The results of Meta analysis showed that there was a significant difference in the incidence of postoperative dislocation between the repaired capsule group and the unrepaired capsule group (OR 0.14, 95% CI 0.08–0.26,  $P = .61$ ,  $I^2 = 0\%$ ; Fig. 2). According to the subgroup analysis of the included studies in the literature, the results of the combined analysis of the five nRCT also showed that there was a significant difference among the five groups (OR 0.12, 95% CI 0.06–0.24,  $P = .72$ ,  $I^2 = 0\%$ ; Fig. 2). The results showed that the repair of posterior capsule is helpful to reduce the incidence of hip dislocation after primary THA (Table 3). It is of great physiological significance to repair the posterior capsule during total hip arthroplasty. Funnel plots illustrated the meta-analysis of the dislocation rate had no obvious publication bias (Fig. 3).

Table 3

## Harris Hip Score (HHS)

Two studies [19, 24] used the Harris Hip Score (HHS), and the results showed significant statistical difference between the 2 groups (MD 1.75, 95% CI 1.19 to 2.32,  $P = .24$ ,  $I^2 = 26\%$ ; Fig. 4). According to the heterogeneity test of the two articles in this study ( $P = .24$ ,  $I^2 = 26\%$ ), it was suggested that there was no heterogeneity among the selected literatures in this study, so we chose the fixed effect model for meta analysis. In order to ensure the accuracy and stability

of the study, we continued to carry out sensitivity analysis. The sensitivity analysis of the two literatures showed that none of them interfered with the results of meta analysis, which meant this study had good stability. The MD values of the two studies were 1.75, 95% confidence interval was  $1.19 \pm 2.32$ . P value ( $p < 0.05$ ) indicated the statistical significant difference between two groups. The results showed that the posterior capsule repair would significantly increase the HHS score after primary THA. The pooled data was showed in the following forest plot (Fig. 4). In this study, funnel plot was drawn to investigate whether publication bias exists. The symmetry of funnel plot means that there is no publication bias. The funnel plot of this study was showed in Fig. 5.

## Complications

Since the effectsize of postoperative complications in three original studies [20, 21, 25] was not be combined, the pooled data of these complications were unable to be obtained. These postoperative complications included the revision for postoperative dislocation, avulsion fracture of the greater trochanter, sciatic nerve palsies. Goldstein, W.M., et al reported two cases of revision for dislocation in the capsule repair group and seven cases of revision for dislocation in the group without capsule repair [20]. White Jr, R.E., et al found that four cases (0.9%) of avulsion fracture of the greater trochanter in the posterior capsule repair group occurred less than 6 weeks after surgery [21]. Tarasevicius, S., O. Robertsson, and H. Wingstrand demonstrated that 2 sciatic nerve palsies in the repair group were directly relevant to posterior suture [25].

## Range of Motion

Three studies [18, 21, 24] assessed range of motion (ROM)of patients. But the pooled data was not obtained because the items of evaluation were different. White Jr, R.E., et al come to a conclusion that average reduction of the passive internal rotation was 50%, and minimum of the passive internal rotation was 25% in the capsule repair group [21]. Suh, K.T., B.G. Park, and Y.J. Choi reported that the ROM was not affected by posterior capsule repair. There was no statistically significant difference between the two groups [24]. Yamaguchi, T., et al suggested there was no significant difference in ROM between the two groups before and after surgery [18].

## Discussion

### Main Results

In any surgical decision, the safety of patients is always important. Considering the uncertainty and controversy in relation to the influence of posterior capsule repair on the incidence of hip dislocation following primary THA, we sought to evaluate the body of evidence linking posterior capsule repair with the risk of hip dislocation following primary THA carrying out a comprehensive systematic review of observational studies and RCTs. This meta-analysis included 8 studies (2 RCTs and 6 nRCTs) that analyzed 4523 patients (4624 hips) and directly compared the clinical effectiveness of the posterior capsule repair group and the control group without posterior capsule repair. The pooled data indicated significant differences between the 2 groups in terms of dislocation rates, HSS, and so on. The approach of posterior capsule repair in total hip arthroplasty is superior to the control group without posterior capsule repair on the basis of the present evidence base. The risk of hip dislocation was higher in the control group without capsule repair, while the complication rate was lower in the posterior capsule repair group. However, those differences might be caused by the significant between-article heterogeneity which was able to affect accuracy of the outcomes in meta-analysis. Random effects model, subgroup analysis, or sensitivity analysis was used to pool data might cut down the effect of heterogeneity. However, it does not eliminate it. The current evidence base—with a good number of methodological inadequacies such as the limited usage of power calculations and poor or absent blinding of both patients and assessors—can cause assessor bias. The evidence base was also guilty of documenting methods of recruitment, thus permitting allocation or recruitment bias. In relation to these factors, the presented evidence base, being substantial in size, may be questioned regarding to its quality.

At present, the primary THA has become a routine treatment for hip diseases. Hip replacement restore patients' function earlier, reduce bedridden complications and mortality [26]. However, with the large-scale popularization of THA surgery, there are more and more complications after THA. The complications of hip replacement can not be ignored, in which postoperative dislocation is catastrophic [27]. The complication of postoperative hip dislocation is second only to aseptic loosening. Currently, the posterior approach is commonly used in total hip arthroplasty, which has the advantages of a short operative time, less bleeding and a shorter hospital stay. However, its disadvantage is also the higher rate of postoperative dislocation [28].

The reasons for postoperative hip dislocation include patient-related factors, such as sex, hip dysplasia, previous hip surgery, patient compliance, and neurologic compromise [29–32]. Currently, it is believed that there are three major reasons for the high incidence of posterior dislocation of the posterolateral incision. Firstly, the short external rotation muscle and the joint capsule are cut off in the posterior approach without careful repair when the incision is closed, resulting in the imbalance of the structural stability of the posterior soft tissue. Secondly, due to insufficient exposure of the surrounding soft tissue in the posterior approach, the prosthesis is easily pushed back when placing the acetabular cup, which changes the forward angle of the acetabular cup. That is to say, the incorrect position of the prosthesis affects the postoperative stability of the hip joint to a great extent. Third, the unskilled surgical technique of the operator will also increase the rate of postoperative dislocation.

Some scholars investigated the reasons for dislocation considering prosthesis. McCollum, D.E. and W.J. Gray thought that the misplacement of acetabular components is considered to be an important cause of postoperative dislocation of the hip joint as well as Coventry, M.B., et al did [6, 33]. Etienne, A., Z. Cupic, and J. Charnley indicated that the dislocation rate after hip arthroplasty is related to the design of prosthesis [34]. Cobb, T.K., B.F. Morrey, and D.M. Ilstrup suggested that an elevated liner can improve the stability of the hip joint after THA, particularly in hips which are at greater risk for the prosthesis dislocation [35]. Sierra, R.J., et al suggested using a 32-mm head in association with posterior joint capsular repair should reduce the rate of dislocation [36]. Hummel, M.T., et al recommended that larger femoral head size and joint capsule tissue repair can increase the stability of the hip joint [9]. McCollum, D.E. and W.J. Gray provided a safe angle for acetabular cup placement to prevent dislocation [6]. Larger femoral head sizes can reduce the incidence of dislocation [37–39]. Other scholars linked the stability of the posterior capsule to the posterior dislocation after THA. Clayton, M.L. and R.G. Thirupathi thought that the brace treatment after total hip arthroplasty can improve the stability and reduce the rate of recurrent dislocations [40]. Wu, H.M. and A.Y. He reached a decision that

posterior capsule repair can reduce the rate of early dislocation after primary THA (within the first six months after surgery) [21]. Two senior authors used the method of posterior soft tissue enhancement to prove that posterior capsule repair can prevent postoperative posterior dislocation of the total hip arthroplasty through a posterior approach[23]. Dixon, M.C., et al reported a simple capsulorrhaphy following a posterior approach which minimized the incidence of postoperative dislocation [41]. Hedley et al. described a method of preserving the posterior capsule for primary hip replacement, with only 2 out of 259 cases of dislocation [42]. Pierchon, F., et al demonstrated that soft tissue imbalance was the major cause of dislocation by CT scan [43]. Stahelin, t. et al. confirmed through experiments that the posterior capsule of the hip joint needs higher torque to repair dislocation [44]. However, some scholars thought that the technique of posterior capsule suture often failed. Stahelin, T., et al, American scholars, placed markers which could not pass through X-rays during the operation, and observed the distance between the two markers through postoperative X-ray plain films. As a result, even though the posterior capsule were repaired in total hip arthroplasty, and most of them were not strong enough to resist the tension of the repair during the healing position, eventually the repair failing. Therefore, in terms of posterior structure suture techniques, it is necessary for us to further explore better techniques to improve the curative effect [45].

## Limitations and Strengths

The limitations of this study are as follows. Firstly, most of the included studies are observational studies (case-controlled studies), in which the reliability of the conclusion needs to be confirmed, because they are more likely to be biased and the number of included literatures is relatively small. Second, there is diversity in the design of the prosthesis such as the size of the femoral head and so on, or it has not been reported in detail, so the heterogeneity is increasing among the included studies. Third, gender, age and specific diseases in the included studies are significantly different. Thus, it also becomes a possible source of heterogeneity. Fourth, some studies have been omitted because of the search strategy we performed. To overcome this limitation, we have consulted researched synonyms, optimized the search strategy, and conducted an extensive search. Fifth, performing a true RCT is difficult. Only 2 of 8 studies were RCTs, in which it was very difficult to realize the blind method. In the most of studies, the method of operation depended on the patient and the doctor; thus, it was difficult to ensure the baseline balance between the 2 groups. Kwon, M.S., et al performed a meta-analysis to compare dislocation rates with and without soft tissue repair after THA. However, the posterior capsule repair had not been specifically described in this systematic literature review [7]. Compared with the above-mentioned meta-analysis, we included some new clinical researches, and our outcomes are more up to date. We performed this study in line with the PRISMA statement, otherwise some authors studied in accordance with the Chinese Cochrane Center. To strengthen our meta-analysis, we need further prospective randomized trials investigating dislocation incidence and other clinical parameters.

## Conclusions

In summary, Our meta-analysis have shown that posterior joint capsule repair can increase joint stability, reduce hip joint dislocation after THA by posterior approach, increase postoperative HHS, and even reduce the amount of bleeding. We look forward to achieving detailed studies with higher quality in the future. In order to resolve this problem, RCTs on the basis of further systematic and comprehensive evaluation are needed to confirm these findings. It is proposed to provide more reliable objective evidence.

### Acknowledgments

One of the first authors (Xiaobo Sun) want to show heartedly thanks to his wife Yuting Liu, who provided much help for grammar expression.

### Declaration of conflicting interest

The authors declare that there are no conflicts of interest.

### Funding

The article received financial support from the High-Level University Construction Project of Guangzhou University of Chinese Medicine(A1-AFD018171Z11068).

## Author Contributions

Conceptualization: Xiaobo Sun, Yirong Zeng.

Literature review and search: Xiaobo Sun, Xingyang Zhu.

Data collection: Xiaobo Sun, Xingyang Zhu.

Data analysis and interpretation: Haitao Zhang, Yuqing Zeng, Wenjun Feng, Jie Li.

manuscript preparation & editing: Xiaobo Sun, Xingyang Zhu.

Supervision: Jianchun Zeng, Yirong Zeng.

## Figures

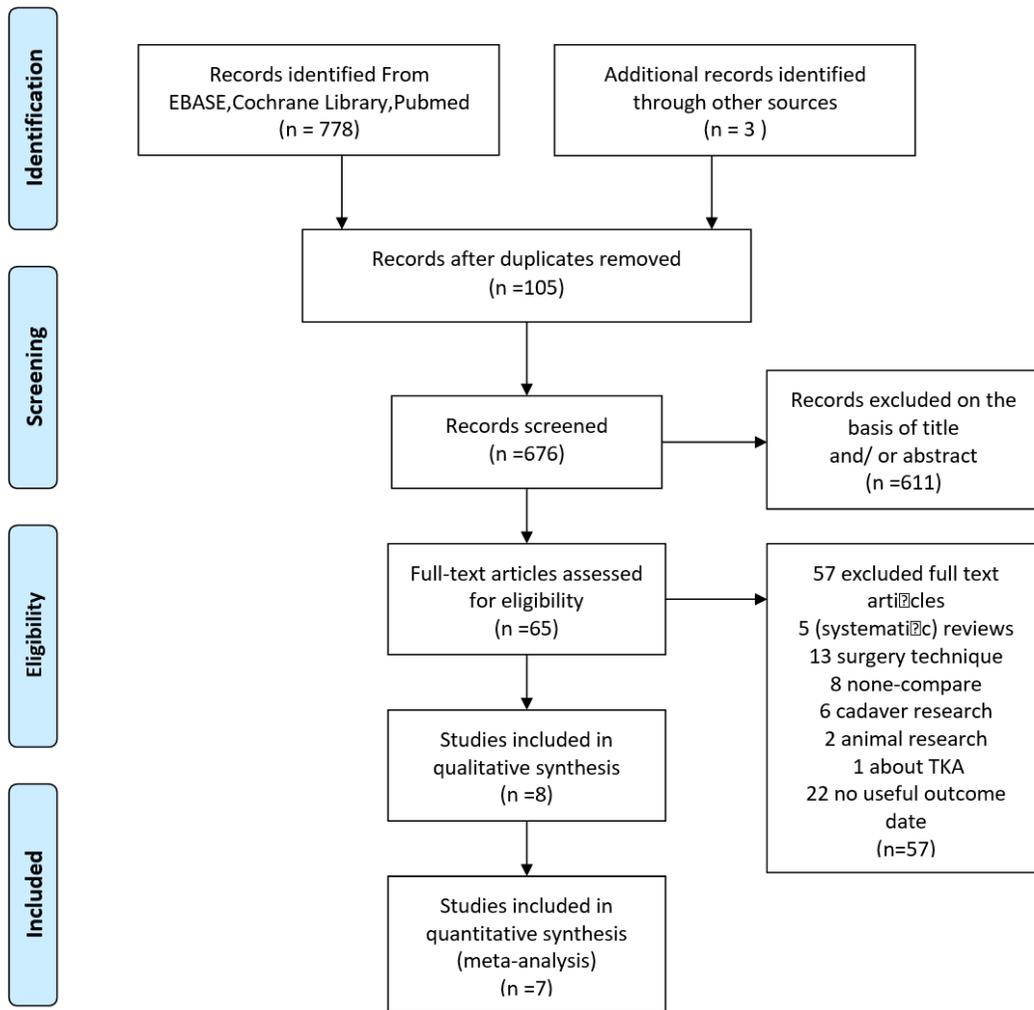

Figure 1

PRISMA flow diagram.

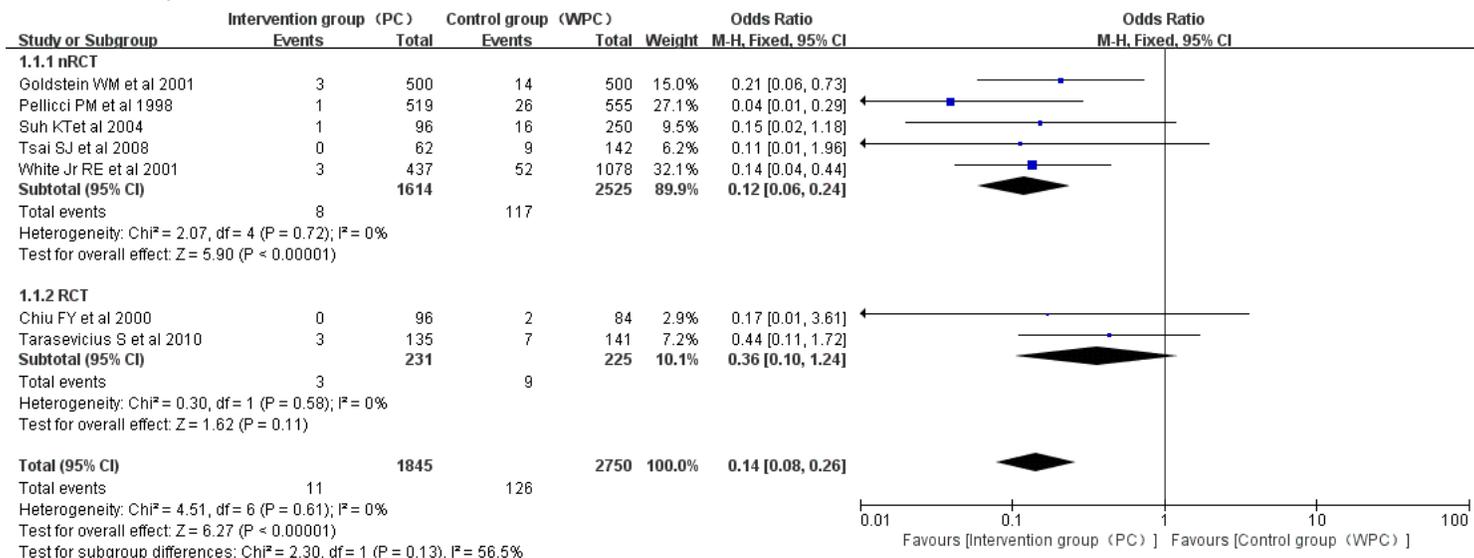

Figure 2

The results of Meta analysis showed that there was a significant difference in the incidence of postoperative dislocation between the repaired capsule group and the unrepaired capsule group (OR 0.14, 95% CI 0.08-0.26, P = .61, I<sup>2</sup> = 0%)

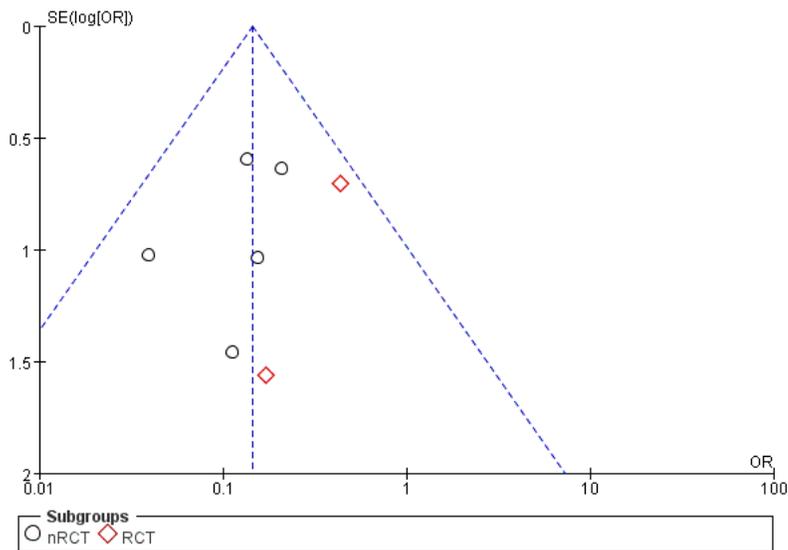

Figure 3

It is of great physiological significance to repair the posterior capsule during total hip arthroplasty. Funnel plots illustrated the meta-analysis of the dislocation rate had no obvious publication bias

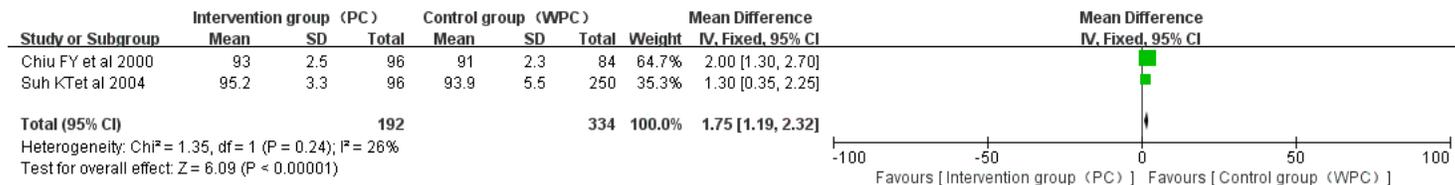

Figure 4

Two studies [19, 24] used the Harris Hip Score (HHS), and the results showed significant statistical difference between the 2 groups (MD 1.75, 95% CI 1.19 to 2.32, P = .24, I<sup>2</sup> = 26%)

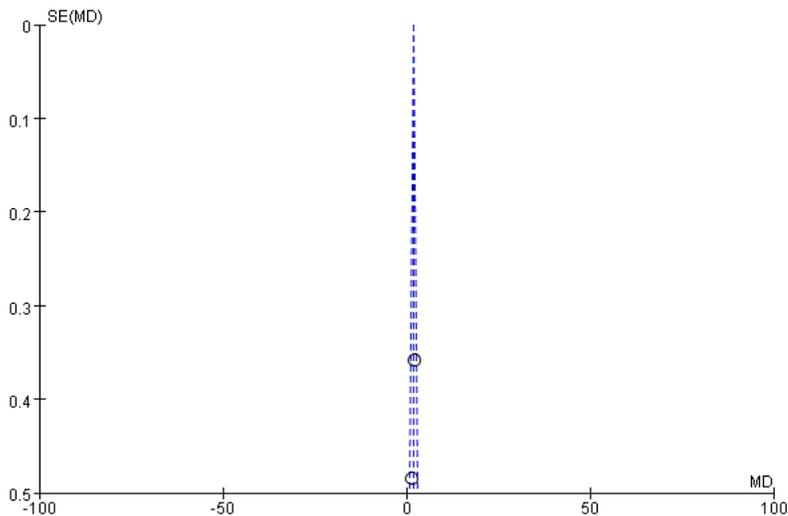

Figure 5

Funnel plot was drawn to investigate whether publication bias exists. The symmetry of funnel plot means that there is no publication bias.
