1 **Big batteries on wheels: converting diesel trains to battery electric can provide significant**
2 **economic, environmental, and grid resilience benefits**

3
4 **Abstract**

5 Nearly all locomotives in the U.S. are propelled by an electric drive that is powered by a diesel
6 generator, the air pollution from which contributes to more than 1,000 premature deaths every
7 year. Dramatic improvements in battery technology plus access to cheap renewable electricity
8 open the possibility of battery-electric rail. Given that locomotives already have an electric drive,
9 converting them to battery-electric primarily requires a battery car, which can be connected
10 directly to the drivetrain. We examine the case for a battery-electric U.S. freight rail sector and
11 find that one heavy-duty battery car can power a typical locomotive for 450 miles, three times the
12 average daily distance travelled by U.S. freight trains. We find that battery-electric trains can
13 achieve cost parity with diesel trains with electricity charging costs under 6 cents/kWh. We
14 illustrate how these costs can be achieved with access to wholesale electricity rates. Converting
15 the fleet to battery-electric would remove 37 million metric tons of carbon dioxide and generate
16 total sector cost savings of \$250 billion over 20 years, while introducing 238 GWh of mobile
17 batteries that could address location-specific grid constraints during extreme events.

1 Based on scientific consensus, global greenhouse gas (GHG) emissions must be reduced 45% from
2 2010 levels by 2030 to limit global warming to 1.5 °C and minimize climate catastrophe.¹ The
3 U.S. freight rail sector provides a unique opportunity for aggressive near-term climate action. It
4 transports more goods than any other rail system in the world² and depends on diesel fuel, which
5 accounts for over 90% of the rail sector's total energy consumption.³ Currently transporting 40%
6 of national intercity freight,⁴ its capacity is projected to double by 2050.⁵ Absent significant
7 changes to its propulsion system, the U.S. freight rail system will be responsible for half of global
8 diesel used in the freight rail sector by the same year.² These diesel locomotives emit 37 million
9 metric tons of CO₂ each year and produce air pollution that causes about 1,500 premature deaths
10 annually, accounting for \$14.1 billion in health damage costs⁶; these damages are almost three
11 times those associated with all U.S. natural gas-based power generation. Despite being more fuel
12 efficient than trucks, the locomotives produce close to twice the air pollution damages as heavy-
13 duty trucks per gallon of diesel consumed owing to less stringent pollution controls on
14 locomotives.^{6,7}

15
16 Efforts to identify zero-emissions pathways for freight rail are underway, with national sector-
17 wide emissions-reductions targets and more stringent Environmental Protection Agency
18 emissions-reductions requirements for the U.S. freight rail sector.⁸ Two pathways have emerged
19 for achieving zero emissions: rail network electrification via catenary and battery-powered
20 locomotives. The catenary approach involves electrifying the entire rail network via overhead lines
21 coupled with grid-scale storage of renewable energy, and it has been more thoroughly
22 investigated.^{9,10} We consider the other pathway based on leveraging recent technological advances
23 to add battery cars to existing diesel-electric locomotives. This approach obviates the infrastructure
24 investment required by a catenary system, and, because of the temporal flexibility of battery
25 charging, it allows rail operators to exploit existing surplus renewable energy sources at low prices.

26
27 Three recent developments support a U.S. transition to battery-electric rail: plummeting battery
28 prices, increasing battery energy densities, and access to cheap renewable electricity for up to 12
29 hours per day. Between 2010 and 2020, battery energy densities tripled and battery pack prices
30 declined 87%.¹¹ Some auto-makers are already achieving lithium-ion battery prices of
31 \$100/kWh.¹² Average industry prices are expected to reach \$100/kWh by 2023¹³ and \$55–
32 \$65/kWh by 2030.¹⁴ At the same time, electricity from renewable sources costs about half as much
33 as electricity from fossil fuels.¹⁵ A few studies have considered battery-electric rail propulsion, but
34 their price estimates are outdated owing to the rapid innovation in battery technology.^{2,16} Previous
35 studies have also relied on average electricity tariffs, which overestimate charging costs because
36 they do not account for potential to charge batteries when surplus renewable electricity is available.

37
38 In this paper, we examine the case for zero-emission, battery-electric propulsion in the U.S. freight
39 rail sector based on current and forecasted energy storage technologies combined with access to
40 renewable energy at industrial rates. We show how retrofitting diesel-electric locomotives with

1 electrically connected battery cars could enable the sector to reduce emissions while realizing
2 economic gains. In addition, the vast pool of locomotive batteries could be deployed to address
3 location-specific grid constraints during extreme events.
4
5

6 **Technical feasibility of battery-electric propulsion**

7 *Powertrain*

8 Over 87% of U.S. locomotives are diesel-electric: a diesel engine drives an electric generator that
9 powers traction motors to drive the axles. Such a train can be converted to battery-electric by
10 adding one or more battery cars with wiring that delivers electricity to the drivetrain. A battery
11 tender car could transmit electricity via cable to the locomotive’s central electrical bus and then
12 transmit that electricity to the traction motors. Alternating current (AC) and direct current (DC)
13 traction motors have different retrofit requirements; both types are used in U.S. locomotives,
14 although AC motors are increasingly common. The DC locomotive requires only cables and a
15 charge controller from the battery tender car, incurring negligible cost. Each locomotive with an
16 AC traction motor would require a transformer (we account for this cost under charging
17 infrastructure in the electricity tariffs) and an onboard inverter for the 3.3-MW traction motor.

18 *Range, size, energy consumption, and charging opportunities*

19 The freight rail sector is almost 10 times more efficient than road-based freight, requiring about
20 1/10th the energy per ton-mile.^{17,18} This advantage provides trains with a margin for adding the
21 battery-related weight, volume, and energy consumption needed to achieve a sufficient daily range
22 while maintaining very high efficiency. In addition, the nature of battery technology and rail
23 operations provides plentiful opportunities for recharging during long hauls. Here we show that
24 adding a single boxcar of battery equipment could enable battery-powered trains to achieve
25 requisite operational ranges while surpassing the energy efficiency of diesel-electric trains.
26

27 Our analysis is based on a typical Class I train operating in California, with four 3.3-MW
28 locomotives pulling 100 boxcars and 7,500 revenue-tons of weight. A typical boxcar has a rated
29 load-carrying capacity of 103 tons,¹⁹ whereas heavy-duty freight cars with additional axles can
30 carry up to 372 tons.²⁰
31

32 To calculate maximum range on one charge, we assume use of lithium ferrous phosphate (LFP)
33 batteries in our base case, because they have a longer cycle life compared with nickel manganese
34 cobalt (NMC) batteries and are more economical given the distances traveled by freight trains (1.5
35 million miles over 20 years).¹⁸ Assuming the current best energy density achieved by LFP batteries
36 (which is lower than NMC energy density but still adequate for the rail sector), a single heavy-
37 duty boxcar could accommodate 44.5 MWh of storage, weighing 293 tons and occupying 4,560
38 cubic feet. This battery capacity is sufficient to power a representative train for approximately 425

1 miles—much farther than existing estimates based on outdated battery energy densities that
2 suggest a single tender car could carry only 6.2 MWh.²¹

3
4 A more realistic range requirement is 150 miles on a single charge, because the average U.S. Class
5 I freight train travels this distance daily.⁷ The 150-mile range requires a 14-MWh battery. Using
6 cell-specific energy figures for LFP batteries and a typical packing fraction (cell weight/pack
7 weight) of 0.8,²² we estimate the total weight of a 14-MWh battery plus inverter at about 103 tons.
8 By assuming the ratio of pack energy density (kWh/L) to pack specific energy (kWh/kg) is the
9 same as at the cell level, we estimate a total battery volume of about 1,380 cubic feet. The
10 combined volume of the battery (1,383 cubic feet) plus inverter (483 cubic feet) is about 40% of
11 the estimated volume of a typical boxcar (4,560 cubic feet).¹⁹ Hence, it is feasible on a weight and
12 volume basis to achieve a 150-mile range using a single typical boxcar equipped with a 14-MWh
13 battery and inverter. A range up to 425 miles could be achieved using a single heavy-duty boxcar
14 before running up against volume constraints.

15
16 The energy consumed by battery freight trains increases by 5% (150-mile range) to 14% (425-mile
17 range) because of the additional battery weight, but it is still about half the energy consumed by
18 diesel trains owing to the high efficiency of all-electric drives. We estimate that trains with a 150-
19 mile range (14-MWh battery) require approximately 0.050 kWh/revenue-ton-mile with LFP
20 technology and 0.046 kWh/revenue-ton-mile with NMC technology. For comparison, an existing
21 estimate of the energy requirements for battery-electric locomotives with regenerative braking is
22 0.02 kWh/revenue-ton-mile.¹⁶

23
24 Battery-powered trains with at least 150 miles of range should have ample opportunity to charge
25 during long routes while remaining on schedule. The average length of a Class I freight haul in the
26 United States is 1,033 miles.³ The typical speed is 20–25 miles per hour (mph) between origin and
27 destination, including all interruptions and stops.²³ Based on the average daily distance of 150
28 miles and a maximum daily distance of at least 500 miles (25 mph for 20 hours), typical freight
29 trains should have opportunity to spend a few hours or more charging every day. Technological
30 advances enable charging rates of 30 minutes to 1 hour for fully charging each cell (1C to 2C
31 charging). Because charging speed is constrained at the cell level, the battery pack can theoretically
32 be charged in 30 minutes to 1 hour. The ability to swap a discharged battery car with a charged
33 battery car would provide additional flexibility. There appears to be significant downtime during
34 which charged cars can be swapped with discharged cars; boxcars typically sit idle for up to 25
35 hours at a time.²³

36 *Charging infrastructure costs*

37 The centralized and scheduled nature of freight rail operation and dispatch can enable high
38 utilization of fast-charging infrastructure, leading to lower costs. We estimate the cost of a 90-MW
39 charging station connected at the transmission level that charges 10 tender cars per day. Using

1 historical prices from the Electric Reliability Council of Texas (ERCOT²⁴) and California
 2 Independent System Operator (CAISO²⁵), we estimate the levelized cost of electricity plus
 3 charging to be between \$0.044/kWh (60% utilization, ERCOT) and \$0.143/kWh (10% utilization,
 4 CAISO) (Figure 1). Phadke et al. (2019) discuss the effect of rate designs on charging costs.²⁶
 5

6
 7 Figure 1. Energy prices (\$/kWh) inclusive of fast-charging infrastructure at various station utilization rates in ERCOT
 8 and CAISO. The ERCOT market assumes rail customers have access to wholesale prices. The illustrative CAISO market
 9 assumes ERCOT’s critical peak pricing (CPP) rate structure and no resource adequacy surcharges. Baseline
 10 assumptions include an 80% depth of recharge, 10 tender cars per station, 1-hour charge time, 7% capital
 11 expenditure revenue return,²⁷ and 10% efficiency losses in power conversion. Station lifetimes are estimated at 20
 12 years. Generation prices are average hourly prices observed for each market for all hours 2017–2019.

13 **Grade capability**

14 Any vehicle’s grade performance depends on its ability to increase power output. In an electric
 15 powertrain, higher power outputs can be achieved by adding motors. Thus, delivering high peak
 16 power is much cheaper for an electric powertrain than for a diesel engine. For example, among
 17 freight truck powertrains, diesel engines cost about six times as much as an electric motor for an
 18 equivalent amount of power.²⁸

19
 20 **Achieving parity with diesel**

21 At near-future battery prices (\$100/kWh), battery-electric trains can achieve parity with diesel-
 22 electric trains if environmental costs are included or rail companies can access wholesale
 23 electricity prices and achieve 50% utilization of fast-charging infrastructure. If both conditions are
 24 achieved, fully electrifying the U.S. freight rail sector will lead to net savings of \$250 billion over
 25 20 years.

26
 27 The charging cost for a battery-electric train primarily includes the cost of the charging
 28 infrastructure and the cost of electricity. Cost of the charging infrastructure is mainly driven by its
 29 utilization factor, and we assume utilization of 50% is possible owing to centralized train
 30 scheduling and swappable battery cars. Electricity costs can be reduced by avoiding charging when

1 electricity prices are high. In certain markets, such as ERCOT, demand and fixed transmission
 2 charges can be avoided by avoiding charging during critical peak pricing (CPP) hours, which occur
 3 during fewer than 50 hours per year.²⁴ Average wholesale generation prices in key organized U.S.
 4 markets for the last 3 years are less than 2 cents/kWh during the lowest-priced 50% of hours in a
 5 day. These prices are projected to decline even further with increasing renewable electricity
 6 penetration.

7
8

9
10 Figure 2. All-inclusive electricity prices (electricity cost plus charging-infrastructure cost) needed to reach diesel
 11 parity based on total cost of ownership (TCO), assuming near-term and projected battery prices with LFP technology
 12 over a 20-year horizon. The solid lines do not include environmental damages, the dashed lines include criteria air
 13 pollutant damages only, and dotted lines include damages from both criteria air pollutants and GHG emissions. At
 14 current wholesale diesel prices of \$2.12/gallon and ignoring environmental damages, all-inclusive electricity prices
 15 would need to approach \$0.057/kWh with battery prices at \$100/kWh and \$0.066/kWh with battery prices at
 16 \$50/kWh to compete with diesel. These estimates are based on a locomotive with a 150-mile range pulling 1,211
 17 revenue-tons with TCO annualized over a 20-year horizon and 3% discount rate. Environmental savings are
 18 estimated using 100% renewable electricity generation.

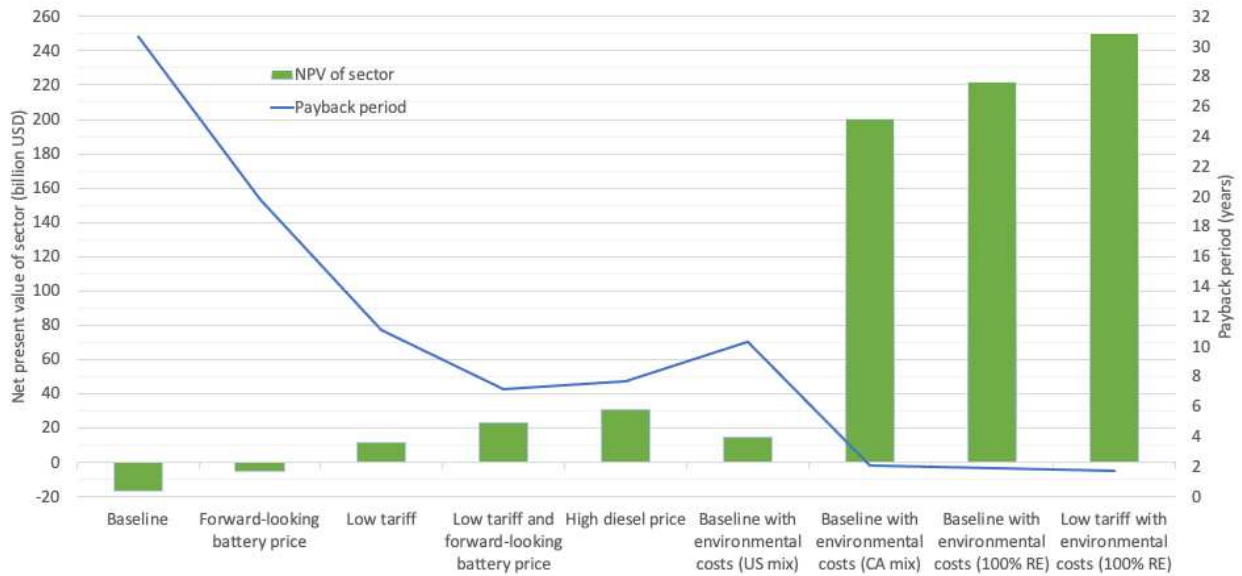

19 Using the energy requirement of 0.050 kWh/revenue-ton-mile for LFP batteries, we estimate
 20 electricity prices necessary to achieve parity with diesel for a battery-powered train with a 150-
 21 mile range pulling 1,211 revenue-tons. To do so, we estimate the capital cost of required battery
 22 capacity and the associated cost of charging, inclusive of the battery weight, cooling requirements,
 23 and inverter. Figure 2 depicts the relationships among battery prices, diesel prices, and electricity
 24 prices needed to motivate a switch to battery-powered trains. To achieve parity with diesel prices
 25 reported by the rail industry (averaging \$2.12/gallon²⁹), all-inclusive electricity prices (electricity
 26 generation plus amortized charging costs) must reach \$0.057/kWh with near-future LFP

1 technology priced at \$100/kWh; this calculation excludes environmental costs. If major markets
2 followed tariff rules like ERCOT's CPP structure, rail freight companies could realize electricity
3 costs (including charging-infrastructure costs) \$0.057/kWh if they reach 35% utilization of fast-
4 charging infrastructure—thus achieving parity with diesel-powered trains.

6 **Sector-wide cost savings**

7 Here we investigate the net present value (NPV) over 20 years to the freight rail sector of
8 converting diesel-electric locomotives into battery-electric, comparing the capital and operating
9 costs along with costs of damages from CO₂ and criteria air pollutants. We use a diesel price of
10 \$2.12/gallon in each scenario. The NPV of switching to battery-electric trains ranges from a cost
11 of \$17 billion in the baseline scenario (25% station utilization) to savings of \$250 billion in the
12 low tariff scenario (50% station utilization) plus consideration of environmental damages with
13 100% renewable electricity use (Figure 3). When the NPV is positive, payback periods range from
14 11 years to just over 1 year per locomotive. Switching to battery-electric propulsion reduces annual
15 CO₂ emissions in the freight rail sector by 6.9 million metric tons using the U.S. power mix, 19.6
16 million metric tons with the California power mix, and 37.3 million metrics tons with 100%
17 renewable electricity, from a baseline of 37.3 million metric tons. Without taking environmental
18 costs into account, the main determinants of the economic returns are the all-inclusive electricity
19 price and the price of diesel fuel. Low battery prices (\$50/kWh) alone are not sufficient to achieve
20 sector-wide payback over 20 years. Even a modest price on the external environmental damages,
21 equivalent to less than \$0.30/gallon of diesel, would be sufficient to make battery-electric cost-
22 competitive with diesel-electric locomotives at a near-future battery price (\$100/kWh) and current
23 electricity-plus-charging-infrastructure prices (\$0.070/kWh).

11

12

Figure 3. NPV of savings over 20 years for the U.S. freight rail sector. The line corresponds to the right y-axis and represents the payback period per locomotive in years. The columns correspond to the left y-axis and represent the NPV of the rail sector using LFP battery technology. All scenarios are based on a 150-mile range for a 3.3-MW locomotive pulling 1,211 revenue-tons. The baseline scenario assumes a \$2.12/gallon diesel price, \$100/kWh battery price, \$0.070/kWh electricity-plus-charging-infrastructure price (assumes 25% station utilization rate), and 3% discount rate. The forward-looking battery price is \$50/kWh. Break-even sector NPV occurs at station utilization rates of 35%, with tariffs at \$0.057/kWh. The low electricity tariff inclusive of fast-charging infrastructure is \$0.048/kWh (assumes 50% station utilization rate). The high diesel scenario uses the baseline case with a \$3/gallon diesel price. Environmental savings are added to the baseline case and are estimated using U.S., California, and 100% renewable electricity mixes.

27

28

29

A battery-electric rail sector will have nearly 240 GWh of modular and mobile storage, providing four advantages over typical grid-scale storage or storage in automotive electric vehicles (EVs). First, locomotives will still have their diesel engines, so their batteries can be available to the power system to manage extreme events. This is not the case with typical EVs, which do not have dual-fuel capabilities. Second, unlike typical grid-scale storage, a train can be moved to address location-specific power system constraints. Third, because the batteries sit on railcars, which can be attached or detached from freight trains seamlessly, they can be flexibly deployed to charge and discharge in optimal locations—charging where prices are low and discharging where the grid is most constrained. Fourth, the four major players in the freight rail industry have maintained a market share of about 85%,³⁰ and each could control large amounts of mobile energy storage, in contrast to fragmented storage ownership that requires highly efficient markets for optimal use. Large-scale modular and mobile storage from trains could support the power system in several ways with appropriate vehicle-to-grid infrastructure, including supplying power to the grid during extreme price or demand events, supporting temporary decommissioning of the transmission and distribution (T&D) infrastructure during wildfire events, and providing emergency backup power

1 to critical loads in the case of outages. Further research is needed to evaluate such possibilities as
2 well as enabling infrastructure and policy.

3 4 **Comparison with electrification via catenary**

5 At the global level, the International Energy Agency compares levelized operating costs per mile
6 for electric-catenary and battery-electric locomotives. Based on this analysis, 9.9-MW battery-
7 electric trains cost \$19.3/train-mile (248-mile range) and \$27/train-mile (466-mile range), and
8 electric-catenary trains cost about \$16/train-mile, not including the capital cost of electric
9 infrastructure.² These estimates represent upper bounds for battery-electric trains, because they
10 assume a battery price of \$250/kWh (almost double current battery prices) and an electricity price
11 of \$0.17/kWh, three times higher than prices already seen for long-term power-purchasing
12 agreements in California.²⁶

13
14 Although electrification via catenary is widespread in Europe and Asia, the context is not directly
15 transferable, because U.S. locomotive power requirements are approximately 10 times greater than
16 requirements in Europe, dramatically increasing the average costs per mile.²¹ Furthermore, the
17 frequent use of double-stack containers in the United States makes catenary requirements
18 problematic; infrastructure would need to be 23.5 feet higher than the tracks to accommodate such
19 trains.²¹ In the United States, costs for catenary construction range from \$8.3 million/mile³¹ to \$50
20 million/mile,¹⁶ excluding the cost of the locomotives. One advantage of battery-electric diesel
21 locomotives is that batteries could simply be attached to existing locomotives with an extra tender
22 car, rather than purchasing new locomotives or upgrading tracks.

23 24 **Discussion**

25 Our analysis provides initial evidence that switching from diesel-electric to battery-electric
26 locomotives could save the U.S. freight rail sector billions of dollars while yielding environmental,
27 health, and grid-resilience benefits. Retrofitting existing diesel-electric locomotives with battery
28 tender cars is a cost-effective technology for transitioning to a zero-emissions rail sector with near-
29 future battery prices and access to wholesale electricity tariffs. In the United States, this approach
30 to freight train electrification is especially attractive, because using a catenary system is much
31 more expensive than in other countries. Other countries also rely heavily on diesel-electric
32 locomotives (e.g. China, Russia, India, and Canada).² Even locations with electrified rail could
33 stand to benefit from mobile grid storage provided by battery tender cars if they experience
34 locationally-constrained grid stress.

35
36 Wholesale U.S. renewable electricity prices have dropped to about 1.5–3 cents/kWh, less than half
37 the long-run marginal cost of electricity from fossil fuel plants.¹⁵ Current electricity-mix emissions
38 intensities are 844 lb CO₂/MWh nationwide³² and 491 lb CO₂/MWh in California.³³ However,
39 because battery cars can charge predominantly when renewable electricity is available, they can
40 exploit low-cost, zero-emission energy. The ability of tariff policies such as real-time pricing to

1 enable use of low-cost renewable electricity for battery-electric trains must be evaluated further.
2 To achieve diesel parity in the short run, such low-cost tariffs are necessary.

3
4 Although they are highly fuel efficient, diesel locomotives generate 1.7 times more air pollution
5 damage per gallon of diesel than diesel trucks do, causing about 1,500 premature deaths every year
6 and accounting for \$14.1 billion in health damage costs.⁶ Our analysis shows that battery-electric
7 trains are cost-effective today if diesel-electric trains internalize the costs of these damages. A
8 commensurate air pollution damage charge or strict air pollution standards that minimize these
9 damages could enable a transition toward battery-electric trains. Such policy options must be
10 evaluated in more detail.

11
12 Although we estimate battery sizes for typical daily freight train ranges, even much smaller
13 batteries can substantially mitigate air pollution damages. Assuming most damages result from the
14 concentration of populations around railyards, train operators may wish to add just enough
15 capacity to run trains on battery power in these areas. BNSF is currently pursuing this approach as
16 part of a project funded by the California Air Resources Board to reduce emissions around
17 railyards.³⁴ Furthermore, although it is feasible to achieve ranges up to 425 miles with a single
18 battery tender car, payload capacity on certain U.S. rail segments, such as bridges, is limited to
19 134 tons per car.³⁵ In light of such constraints, it may make more sense to forego additional
20 revenue-tons by adding extra battery tender cars rather than increasing the maximum range for a
21 single car. Further research could provide insight into optimal ranges for different trip lengths and
22 locations.

23
24 Lastly, planning and deploying a bidirectional charging infrastructure to optimize grid services via
25 charging and discharging of battery-electric cars will be required to capture the full economic and
26 environmental value of battery-electric trains. Further research is needed on the deployment and
27 operation of such infrastructure.

28 29 **Methods**

30 We estimate the levelized cost of ownership to convert the U.S. freight rail sector from diesel to
31 battery-electric locomotives in dollars per revenue-ton-mile. We consider scenarios that
32 progressively improve the case for battery-electric locomotives. We begin with a baseline scenario
33 of average charging costs (which capture both electricity tariffs and costs of installing fast-
34 charging infrastructure), no consideration of environmental benefits, and no further decline in
35 battery prices. This scenario represents the economics without any policy intervention in
36 approximately the year 2023. We then consider scenarios of low charging costs (reflecting cases
37 in which low-cost renewable electricity can be used), further declines in battery prices as projected
38 by most analyses, and inclusion of the value of environmental benefits. Low renewable electricity
39 prices can be achieved by implementing policies such as real-time pricing, with tariffs linked to
40 wholesale market prices, and environmental regulations that capture the economic value of

1 environmental benefits.²⁶ Such prices are already observed, for example, in California during
 2 certain times of the day. The main departure from previous estimates are the dramatic increases in
 3 battery energy densities coupled with recent and ongoing decreases in battery prices.

4
 5 **Scenario**
 6 The key baseline input parameters used in this analysis, which represent current and near-term
 7 forecasted technology and prices (in 2019 U.S. dollars), are listed in Table 1. We estimate battery
 8 size based on the specifications of trains currently operating in California, representative of line-
 9 haul trains consisting of four 3.3-MW locomotives carrying 7,500 revenue-tons.¹⁶

10
 11 *Table 1. Baseline assumptions for typical U.S. train*

Train characteristics		
Power rating of locomotive ¹⁶	3.3	MW
Power rating of train (4 locomotives)	13.2	MW
Train pull weight ¹⁶	7,500	revenue-tons
Locomotive pull weight	1,875	revenue-tons
Efficiency of diesel engine ¹⁶	0.39	
Energy intensity of freight rail sector	293	BTU/ton-mile
Energy requirements for diesel-powered train ¹⁶	0.086	kWh/ton-mile
Range	150	miles
Volume of 48-foot boxcar ¹⁹	4,560	cubic feet
Payload capacity of standard boxcar ¹⁹	103	tons

12
 13 **Battery size**
 14 We estimate necessary battery size using bottom-up calculations for the representative train. Using
 15 the average energy requirements of the diesel baseline at 0.086 kWh/ton-mile, and the relative
 16 efficiency of battery power over diesel engines, we estimate that each locomotive requires a battery
 17 of 14 MWh using LFP technology to pull 1,875 revenue-tons for 150 miles. Table 2 describes the
 18 input parameters for determining battery pack size.

19

1 *Table 2. Input parameters for estimating battery pack size*

Energy requirements for battery-powered train			
Heat value of diesel ³⁶	10.6		kWh/L
Battery pack assumptions	<i>NMC</i>	<i>LFP</i>	
Cell specific energy ³⁷	0.308	0.21	kWh/kg
Packing fraction ²²	0.8	0.8	
Cell energy density ³⁷	0.754	0.47	kWh/L
Battery roundtrip efficiency ³⁸	0.9	0.95	
Efficiency relative to diesel	2.31	2.44	
Depth of discharge ³⁹	0.9	0.8	
Cooling requirements			
Battery tender car floor area	567		square feet
Temperature change	15		degrees Celsius
Operating time	12		hours per day
Cooling load	19,000		BTU/hour

2
3 We estimate battery size using LFP technology, which has a lower energy density but longer
4 lifetime than NMC technology. In the rail sector, the opportunity costs of larger batteries are
5 significantly lower than in the trucking sector. Batteries incur an efficiency loss due to the need to
6 cool the battery system. We upsize the battery to accommodate air conditioning requirements for
7 the battery tender car. We estimate the energy required to cool the entire volume of the boxcar by
8 15 °C over 12 hours of the day. We assume that the locomotive still has its existing diesel engine
9 and fuel tank.

10
11 ***Charging cost***

12 We adapt the method from previous research on TCO for electrifying the trucking sector²⁶ to the
13 rail sector, estimating the unit cost of charging as the total of the levelized cost of equipment, the
14 cost of generation, and the cost of T&D. Table 3 describes the inputs used to estimate unit charging
15 costs for the ERCOT market. Following their method,²⁶ we model the unit charging cost for a retail
16 customer who is able to access wholesale energy prices in ERCOT territory. This scenario is
17 realistic under current regulations. The levelized cost of equipment, in this scenario, is defined as
18 the minimum price per unit of energy delivered (kWh) that a charging service provider should
19 charge the consumer to break even on the investment in charging equipment and grid
20 interconnection.²⁶

1 *Table 3. Input parameters for levelized unit charging costs in existing ERCOT and illustrative*
 2 *CAISO market*

Cost component	Description	Cost	Description	Cost	Units
	ERCOT		CAISO		
Electricity generation	Price a retail electric provider would pay to pass through the real-time price to a retail customer, based on ERCOT prices 2017–2019 ²⁴ and ERCOT day-ahead market clearing prices for capacity ⁴⁰	26.3	Illustratively modeled as the price an energy service provider would pay to pass through the real-time price to a direct-access customer, not including resource adequacy payments, based on CAISO real-time prices 2017-2019, ²⁵ CA renewable portfolio standards, ⁴¹ REC prices ⁴² , and CAISO fees ⁴³	32.9	\$/MWh
Transmission and distribution	T&D charges paid by a transmission-connected customer in Oncor service territory, charging only at non-critical-peak times ⁴⁴	0.3	T&D charges paid by a transmission-connected customer in Oncor service territory, charging only at non-critical-peak times ⁴⁴	0.3	\$/MWh
Electrical equipment	Average of best-case electric vehicle supply equipment (EVSE) costs, taken to be (1) the balance of system (BOS) costs of grid-tied storage, and (2) industry-projected EVSE costs, based on utility-scale solar + storage BOS costs ⁴⁵ and inverter lifetime ⁴⁶			18.2	\$/MWh
Grid connection	Average U.S. grid connection cost for utility-scale solar photovoltaic (PV) projects ⁴⁷			5.5	\$/MWh
Operations and maintenance	Cost of (1) inverter maintenance for a PV plant, (2) preventive maintenance and inspection, averaged for both an existing electric bus charging station and the electrical/wiring inspection costs of a PV plant, and (3) estimated structural maintenance ⁴⁶			4.8	\$/MWh
Installation	Installation costs associated with grid-tied storage, grid-connected storage cost of installation, labor, and equipment, EPC overhead, and interconnection ⁴⁵			7.5	\$/MWh
Capital	Return owed on capital investment, based on California Investor Owned Utilities (IOU) rates of return ²⁷			7	%

Table 4 reports the historical and projected wholesale energy price patterns for two energy markets. We estimate the percentage of hours observed under a specific price point as the average hourly wholesale price observed for all days in the timeframe. Already, the 12 cheapest hours of the day in both markets are below \$23/MWh (used for the base case in the NPV calculations). Combined with a 35% charging station utilization rate, battery-electric locomotives can achieve parity with diesel-electric locomotives.

Table 4. Historical wholesale energy prices in ERCOT and CAISO

	Historical (2017–2019)	
	CAISO ²⁵	ERCOT ²⁴
% of hours under \$30/MWh	60	76
% of hours under \$45/MWh	87	91
Avg. price of 8 cheapest hours of the day (\$/MWh)	17.5	16.9
Avg. price of 12 cheapest hours of the day (\$/MWh)	20.3	18.4
Avg. price of 8 cheapest hours on the most expensive day (\$/MWh)	69.4	44.3

Note: These prices reflect only the price of generation, and do not include fast-charging infrastructure, T&D, or demand charges

11 ***Sector-wide cost of ownership***

12 We use a straightforward energy balance approach using national data on train revenue-ton-miles
 13 and diesel fuel consumption to estimate the approximate energy requirements to transport the same
 14 tonnage under battery-electric propulsion. To ensure that our sector-wide results do not
 15 overestimate electricity requirements, we use the national average estimates to calculate sectoral
 16 costs, benefits, and emissions. Whereas a representative line-haul locomotive may pull 1,875
 17 revenue-tons, the national average Class I freight locomotive travels 150 miles per day and carries
 18 only 1,211 revenue-tons. Our estimates suggest that this load requires about a 9.1-MWh battery
 19 per locomotive, after adjusting for battery weight and cooling requirements.

20
 21 Each locomotive with an AC traction motor requires an onboard inverter for the 3.3-MW traction
 22 motor at \$70/kWh.⁴⁵ Table 5 lists the key baseline input parameters used in this analysis, which
 23 represent current and near-term forecasted prices. We borrow existing methods to estimate
 24 charging costs that include electricity and fast-charging infrastructure costs, where the equipment
 25 cost per kWh decreases as a function of capacity utilization. Assuming a capacity utilization rate
 26 of 50% (train batteries are charging for approximately 12 of 24 hours each day) amortized fast-
 27 charging infrastructure costs plus energy are \$0.048/kWh. We estimate a low-cost scenario of
 28 \$0.048/kWh (50% capacity utilization) and a high-cost scenario of \$0.07/kWh (25% capacity
 29 utilization) inclusive of the levelized cost of fast-charging infrastructure. Given the flexibility in
 30 charging times, we would expect that train operators would have access to the lowest energy prices.

31

1 We calculate environmental impacts by comparing diesel emissions to baseline emissions from
 2 electricity generation using three different power mixes: the U.S. average, the California power
 3 mix, and 100% renewables.

4
 5

Table 5. Input parameters for TCO model

Unit capital cost components		
Battery life ^a	2,000 – 4,000	cycles
Cost of battery ¹³	50 –100	\$/kWh
Cost to replace battery	50	\$/kWh
Cost of inverter ⁴⁵	70	\$/kWh
Cost of standard boxcar ⁴⁸	135,000	\$
Inverter size	3.3	MW
Unit fuel cost components		
Electricity price (inclusive of fast-charging infrastructure)	0.048 – 0.070	\$/kWh
Cycles per day	1	
Diesel price ²⁹	2.12 – 3	\$/gal
Avg. fuel consumption per locomotive per day ¹⁸	384	gallons
Unit air pollution costs		
Air pollution damages per diesel locomotive ⁶	1,458	\$/day
Damages of locomotive sector across all air pollutants ⁶	14.1	billion \$
Air pollution damages from coal-based electricity generation ⁶	135	billion \$/year
Air pollution damages from gas-based electricity generation ⁶	5.55	billion \$/year
Coal-fired generation (2019) ⁴⁹	966	billion MWh/year
Gas-fired generation ⁴⁹	1,582	billion MWh/year
Unit GHG emissions cost components		
Marginal damage of CO ₂ emissions ⁵⁰	52	\$/metric ton CO ₂
Diesel to CO ₂ conversion factor ⁵¹	10.21	kg CO ₂ /gal
Emissions intensity of coal-fired electricity ^{52,53}	210.4	lb CO ₂ /million BTU
Emissions intensity from gas-fired electricity ⁵²	117	lb CO ₂ /million BTU
Emissions intensity of U.S. power mix ³²	844	lb CO ₂ /MWh
Emissions intensity of California power mix ³³	491	lb CO ₂ /MWh
<i>Note: All prices are listed in 2019 U.S. dollars.</i>

Figures

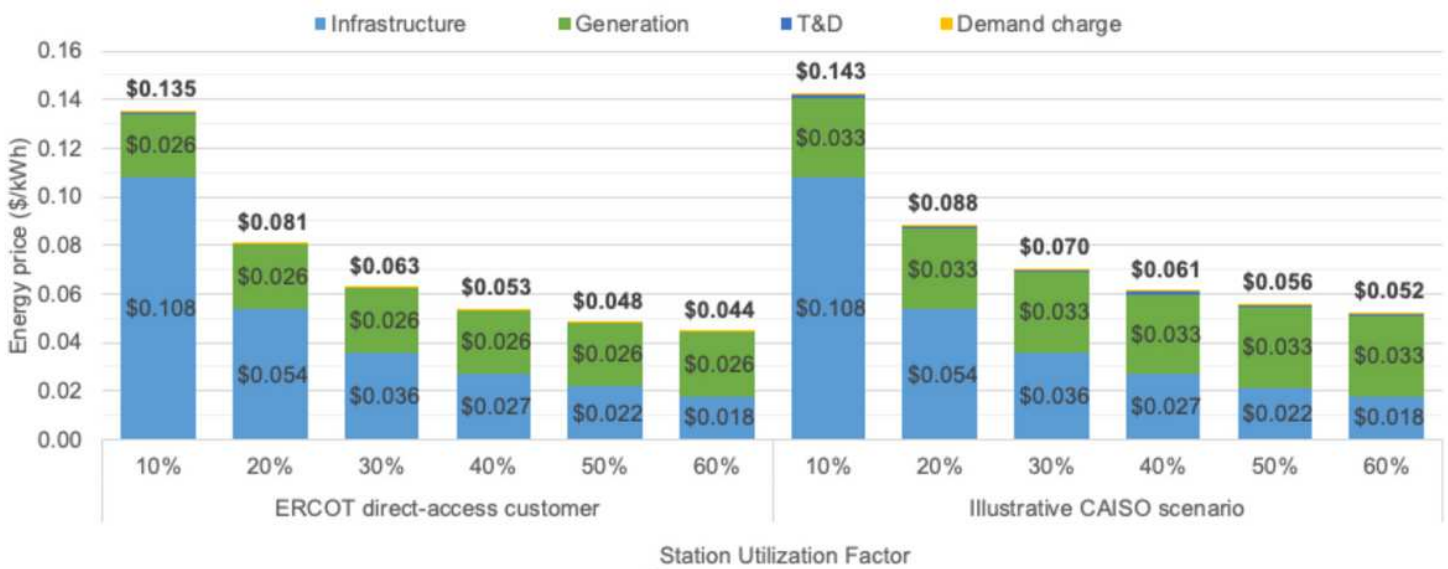

Figure 1

Energy prices (\$/kWh) inclusive of fast-charging infrastructure at various station utilization rates in ERCOT and CAISO. The ERCOT market assumes rail customers have access to wholesale prices. The illustrative CAISO market assumes ERCOT’s critical peak pricing (CPP) rate structure and no resource adequacy surcharges. Baseline assumptions include an 80% depth of recharge, 10 tender cars per station, 1-hour charge time, 7% capital expenditure revenue return,²⁷ and 10% efficiency losses in power conversion. Station lifetimes are estimated at 20 years. Generation prices are average hourly prices observed for each market for all hours 2017–2019.

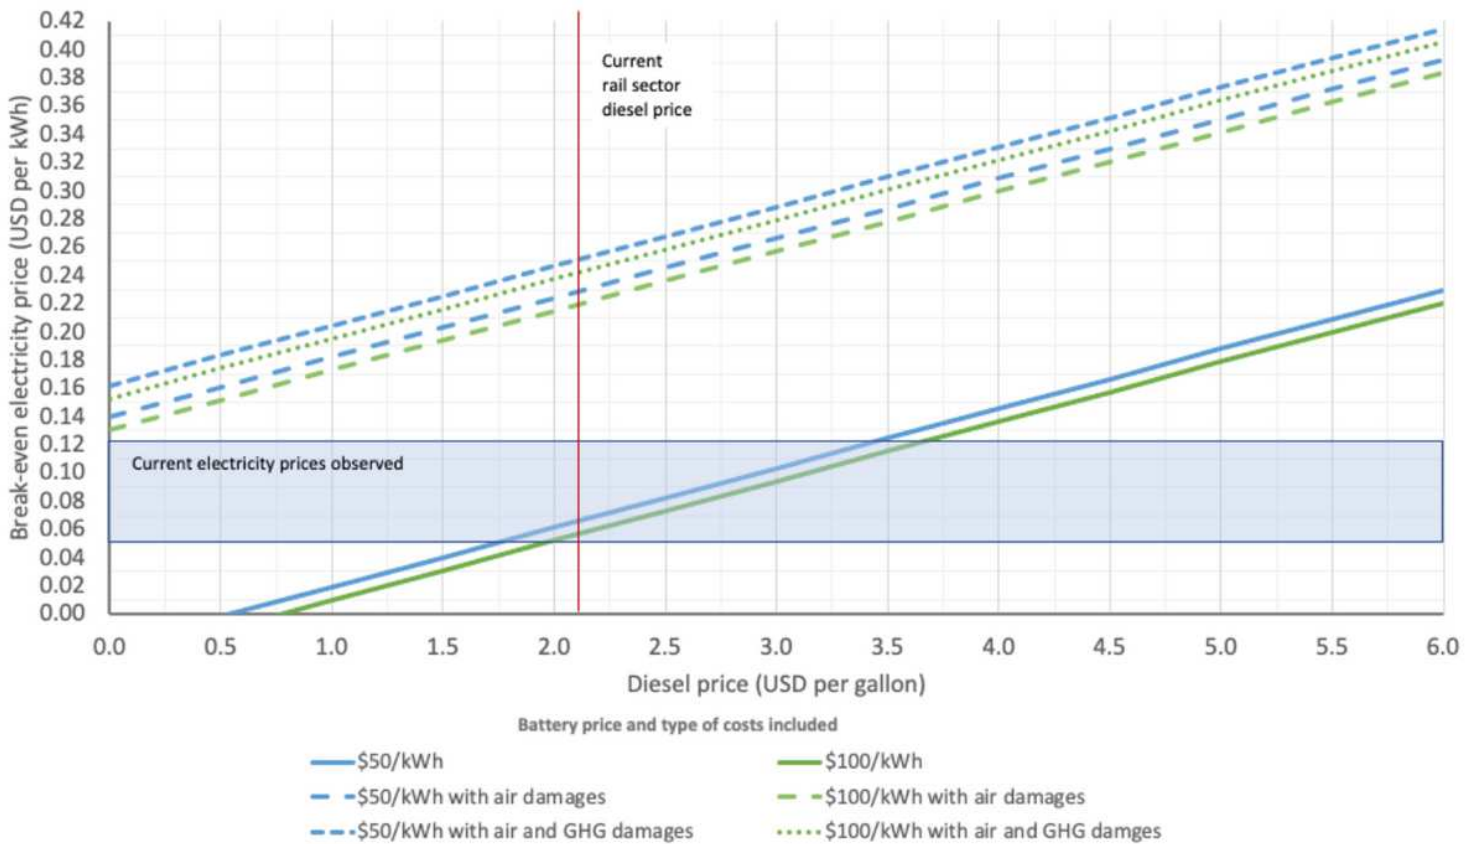

Figure 2

All-inclusive electricity prices (electricity cost plus charging-infrastructure cost) needed to reach diesel parity based on total cost of ownership (TCO), assuming near-term and projected battery prices with LFP technology over a 20-year horizon. The solid lines do not include environmental damages, the dashed lines include criteria air pollutant damages only, and dotted lines include damages from both criteria air pollutants and GHG emissions. At current wholesale diesel prices of \$2.12/gallon and ignoring environmental damages, all-inclusive electricity prices would need to approach \$0.057/kWh with battery prices at \$100/kWh and \$0.066/kWh with battery prices at \$50/kWh to compete with diesel. These estimates are based on a locomotive with a 150-mile range pulling 1,211 revenue-tons with TCO annualized over a 20-year horizon and 3% discount rate. Environmental savings are estimated using 100% renewable electricity generation.

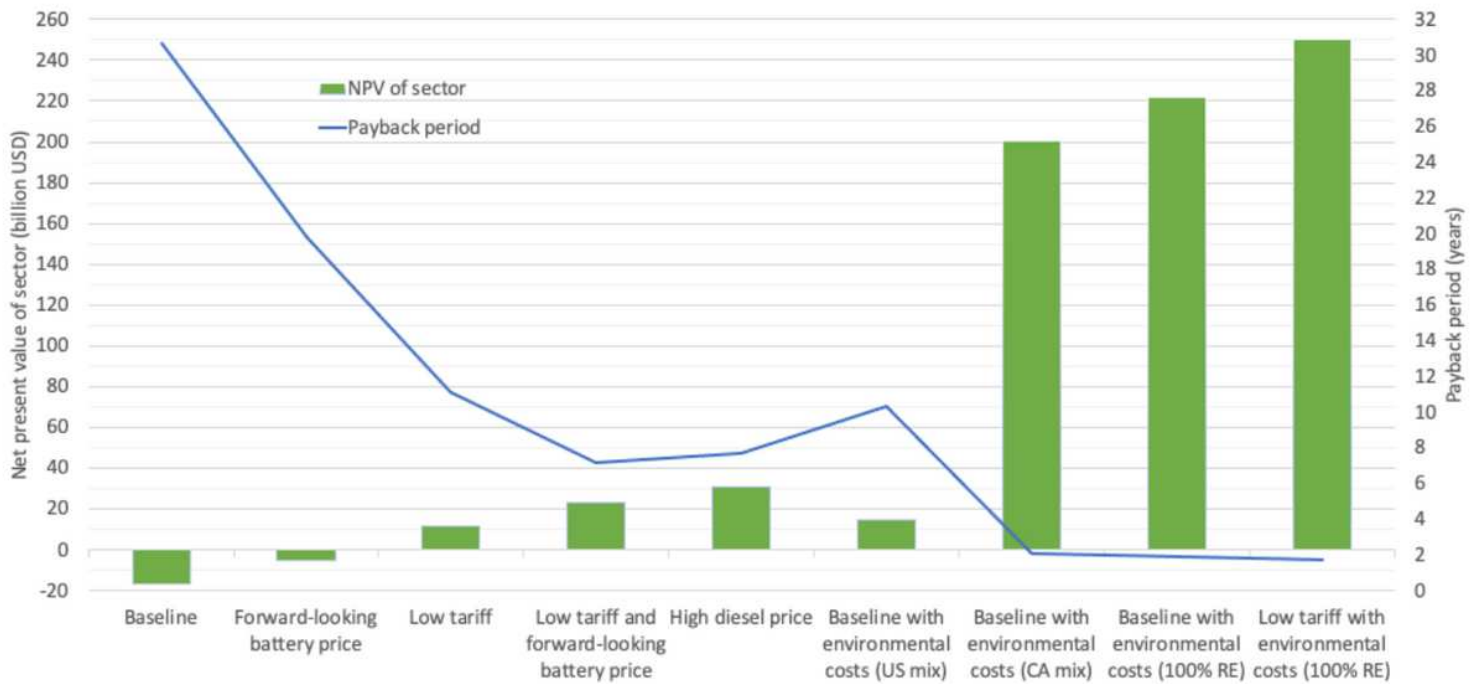

Figure 3

NPV of savings over 20 years for the U.S. freight rail sector. The line corresponds to the right y-axis and represents the payback period per locomotive in years. The columns correspond to the left y-axis and represent the NPV of the rail sector using LFP battery technology. All scenarios are based on a 150-mile range for a 3.3-MW locomotive pulling 1,211 revenue-tons. The baseline scenario assumes a \$2.12/gallon diesel price, \$100/kWh battery price, \$0.070/kWh electricity-plus-charging-infrastructure price (assumes 25% station utilization rate), and 3% discount rate. The forward-looking battery price is \$50/kWh. Break-even sector NPV occurs at station utilization rates of 35%, with tariffs at \$0.057/kWh. The low electricity tariff inclusive of fast-charging infrastructure is \$0.048/kWh (assumes 50% station utilization rate). The high diesel scenario uses the baseline case with a \$3/gallon diesel price. Environmental savings are added to the baseline case and are estimated using U.S., California, and 100% renewable electricity mixes.
