Heterogeneous catalysts play a key role in the chemical and energy industries[1]. To date, most industrial-scale heterogeneous catalytic reactions have relied on nanocatalysts[2,3]. However, despite significant progress from theoretical, experimental and computational studies[4-18], identifying the active sites of alloy nanocatalysts remains a major challenge. This limitation is mainly due to an incomplete understanding of the three-dimensional (3D) atomic and chemical arrangement of different constituents and structural reconstructions driven by catalytic reactions[19-22]. Here, we use atomic electron tomography[23] to determine the

3D local atomic structure, surface morphology and chemical composition of 11 Pt alloy nanocatalysts for the electrochemical oxygen reduction reaction (ORR). We reveal the facet, surface concaveness, structural and chemical order/disorder, coordination number, and bond length with unprecedented 3D atomic detail. The experimental 3D atomic coordinates are used by first-principles trained machine learning to identify the active sites of the nanocatalysts, which are corroborated by electrochemical measurements. A striking feature is the difference of the ORR activity of the surface Pt sites on the nanocatalysts by several orders of magnitude. Furthermore, by analyzing the structure-activity relationship, we formulate an equation named the local environment descriptor to balance the strain and ligand effects and gain quantitative insights into the ORR active sites of the Pt alloy nanocatalysts. The ability to determine the 3D atomic structure and chemical composition of realistic nanoparticles coupled with machine learning could transform our fundamental understanding of the catalytic active sites and provide a guidance for the rational design of optimal nanocatalysts.

PtNi and Mo-doped PtNi (Mo-PtNi) nanocatalysts with varying Ni concentration were synthesized on carbon black / nanotubes using an efficient one-pot approach[24,25] (Methods). The nanocatalysts on carbon black were activated through a cyclic voltammetry test, and the ORR specific activities of PtNi and Mo-PtNi were measured to be 4.8 and 9.3 mA/cm^2 at 0.9 V$_{RHE}$, respectively (Supplementary Fig. 1). The increase of the ORR activity with Mo dopants is consistent with previous reports[24-26]. Atomic electron tomography (AET) experiments were performed on 11 nanocatalysts embedded in carbon nanotubes with an annular dark-field scanning transmission electron microscope (Supplementary Figs. 2-6 and Table 1). By using a low-exposure data

49   acquisition scheme[27] and minimizing the electron dose, the structure of the nanocatalysts

50   were consistent throughout the experiment (Supplementary Fig. 7). After pre-processing,

51   3D reconstruction, atom tracing and refinement[23,28] (Methods and Supplementary Fig. 8),

52   the 3D atomic coordinates and chemical composition of the nanocatalysts were

53   determined (Fig. 1), where the voxel size was calibrated by an extended x-ray absorption

54   fine structure measurement (Methods). The total number of the Pt and Ni atoms in each

55   of the 11 nanocatalysts ranges from 4,281 to 14,172 (Supplementary Table 1). Due to a

56   very small fraction (~0.4%) of Mo dopants[25], AET is presently not sensitive enough to

57   distinguish them from the Ni or Pt atoms, but this limitation will not impact the

58   conclusions of this study.

59   Figure 1, Supplementary Fig. 9 and Video 1 show the 3D surface morphology,

60   atomic structure and chemical composition of the 11 PtNi and Mo-PtNi nanocatalysts.

61   Elemental segregation was observed on the surface and in the interior of the nanoparticles.

62   The surface layer mainly consists of Pt atoms, forming (100), (110), (111) and a small

63   fraction of high-index facets. From the experimental 3D coordinates, we quantitatively

64   characterized the surface concaveness, structural and chemical order/disorder,

65   coordination number (CN), and surface bond length (Methods). Although the majority of

66   the nanoparticles exhibit an octahedral morphology, we observed surface concaveness,

67   structural and chemical disorder to varying degrees in all these nanocatalysts (Fig. 2a-c).

68   We revealed that the Mo dopants increase the surface concaveness and the structural

69   disorder and preserved more subsurface Ni atoms (Fig. 2a, b and d). The CN of the surface

70   Pt sites ranges from 4 to 11 with the peak at CN = 9 (Fig. 2e). The average surface Pt-Pt

71   bond length was measured to be 2.77±0.16 Å and 2.75±0.19 Å for PtNi and Mo-PtNi,

72   respectively (Fig. 2f), which are correlated with the subsurface Ni composition. The

73   increase of the subsurface Ni composition reduces the average surface Pt-Pt bond length

74   (Fig. 2g).

75   The experimentally determined 3D atomic coordinates were used by first-

76   principles trained machine learning (ML) to identify the ORR active sites of the

77   nanocatalysts (Methods). The ORR takes place primarily through a four-step

78   electroreduction mechanism $O_2 + 4\,(H^+ + e^-) \rightarrow 2H_2O$, in which the surface hydroxyl

79   group (OH) is an intermediate[14]. Density functional theory (DFT) calculations have

80   revealed that the ORR activity follows the Sabatier principle[11,14,29], that is, the optimal

81   catalysts have the adsorption energy of the intermediates neither too strong nor too weak.

82   When the OH binding energy (BE_{OH}) is about 0.13 eV weaker than that of bulk Pt(111),

83   the optimal ORR activity is reached[11,14]. As it is computationally impractical to perform

84   DFT calculations for all the 11 nanocatalysts each with several thousands of atoms, we

85   used a DFT-trained ML method to determine the OH binding energy for the

86   experimentally measured surface Pt sites (Methods). We first constructed 207 3D PtNi

87   atomic models each surrounding a surface Pt site with a different local environment

88   (Supplementary Fig. 10). After calculating the BE_{OH} for the 207 Pt sites by DFT, we

89   randomly chose 134 sites to train the ML method and then used it to identify the BE_{OH} of

90   the 73 test Pt sites. A quantitative comparison between the DFT calculated and ML

91   identified BE_{OH} is shown in Supplementary Fig. 11, indicating that ML accurately

92   predicted the BE_{OH} with a root mean square error (RMSE) of 0.05 and 0.07 eV per site

93   for the 134 training and 73 test Pt sites, respectively.

94   After training and validating the ML method, we applied it to evaluate the ORR

95   activity for the experimentally measured surface Pt sites of the PtNi and Mo-PtNi

96   nanocatalysts. By referring BE_{OH} to the OH binding energy of Pt(111)[14], we identified

97 the ORR activity for all the surface Pt sites (Methods). The average catalytic activities of

98 the 11 nanocatalysts agree well with the electrochemical measurements (Fig. 3a),

99 showing the robustness of using DFT-trained ML to identify the ORR activity for the

100 experimental 3D atomic coordinates. Figure 3b, c, Supplementary Video 2, and

101 Supplementary Fig. 12 show the ORR activity maps of the surface Pt sites of the 11 PtNi

102 and Mo-PtNi nanocatalysts. We observed that the ORR activity of the surface Pt sites

103 varies by several orders of magnitude. While the majority of the surface Pt sites have a

104 low catalytic activity, there are a very small fraction of highly active sites (yellow atoms

105 in Fig. 3b and c). Figure 3d-i shows six representative highly active sites on the PtNi and

106 Mo-PtNi nanocatalysts, each of which exhibits a distinct 3D local environment such as

107 different CN, neighbouring Ni atoms and surface morphology. This observation indicates

108 that quantitative characterization of the 3D local atomic environment is critical to the

109 understanding of the active sites of nanocatalysts.

110   To gain quantitative insights into the ORR active sites of the nanocatalysts, we

111 performed a comprehensive analysis of the structure-activity relationship at the individual

112 atom level. We fit a large number of experimentally measured structural and chemical

113 properties such as the surface concaveness, CN, Pt-Pt bond length, structure/chemical

114 order parameters, strain/ligand effects, and others to the ΔBE_{OH} of the 26,246 surface Pt

115 sites of the PtNi and Mo-PtNi nanocatalysts (Methods and Supplementary Tables 2). By

116 minimizing the RMSE between the calculated and ML-determined ΔBE_{OH}, we derived

117 the local environment descriptor (LED) (Methods), which is dimensionless and defined

118 as,

$$LED = NN^{Pt} \cdot e^{-a_1 \cdot \varepsilon} + a_2 \cdot \overline{CN}^{Ni}, \quad (1)$$

120   Where NN^{Pt} is the number of the nearest-neighbour Pt atoms of a surface Pt site, $\varepsilon =$

121   $\frac{\overline{d}_{Pt}-d_0}{d_0}$ is the local strain with $\overline{d}_{Pt}$ the average Pt-Pt bond length around the surface Pt site

122   and d_0 the Pt-Pt bond length (2.75 Å) for Pt nanocrystals, $\overline{CN}^{Ni} = \sum_i \frac{CN_i^{Ni}}{CN_{max}}$ is the

123   generalized CN of the considered Pt with Ni atoms[11,30], CN_i^{Ni} is the CN of the ith Ni atom,

124   $CN_{max} = 12$ is the CN in bulk Pt, a_1 and a_2 are two fitting constants related to the strain

125   and ligand effects, respectively. Our quantitative analysis showed that NN^{Pt}, $\overline{d}_{Pt}$ and

126   $\overline{CN}^{Ni}$ are more relevant to the ORR activity of the nanocatalysts than other properties

127   such as surface concaveness, structural and chemical order/disorder (Methods). By fitting

128   the LED to the BE_{OH} of all the surface Pt sites relative to the OH binding energy of

129   Pt(111), we obtained the distribution of the ORR activity as a function of the LED,

130   showing a volcano plot with the peak at LED = 9.7 (dashed red line in Fig. 3j). The RMSE

131   of the fitting is 0.104 eV with $a_1 = 1.985$ and $a_2 = 1.075$. The small RMSE value indicates

132   the robustness of the structure-activity fitting analysis. Figure 3k, l, Supplementary Fig.

133   13, and Video 2 show the activity maps of the 11 PtNi and Mo-PtNi nanocatalysts based

134   on the LED, which agree well with ML-identified activity maps (Fig. 3b, c and

135   Supplementary Fig. 12). As specific examples, the six highly active sites shown in Fig.

136   3d-i has the LED between 9.7 and 9.79.

137   To better understand the LED, we considered a Pt(111) surface without strain.

138   From Eq. (1), we calculated LED = 9, which is located on the left-side of the peak of the

139   volcano plot (Fig. 3j). If a nearest-neighbour surface Pt atom is substituted by a Ni atom,

140   the first term of Eq. (1) decreases by 1, but the second term increases by a number smaller

141   than 1, making LED smaller than 9 and decreasing the activity. If the substitutional Ni

142   atom is in the subsurface, the CN of the Ni is 12 and the second term increases by a

143 number larger than 1 as $a_2 > 1$, making LED larger than 9. Furthermore, compressive

144 strain, induced by the decrease of the average Pt-Pt bond length, also increases LED.

145 Consequently, with LED < 9.7, both subsurface Ni atoms and compressive strain increase

146 the ORR activity. When LED reaches the peak of the volcano plot (LED = 9.7 in Fig. 3j),

147 further increasing the subsurface Ni atoms and the compressive strain reduces the ORR

148 activity. Thus, the LED quantitatively balances the strain and ligand effects to optimize

149 the ORR activity of PtNi and Mo-PtNi nanocatalysts.

150   Our experimental results revealed that statistically Mo-PtNi has a shorter surface

151 Pt-Pt bond length and a broader distribution than PtNi (Fig. 2f), indicating that Mo-PtNi

152 presents a larger compressive strain than PtNi. Additionally, Mo-PtNi preserves more

153 subsurface Ni atoms than PtNi (Fig. 2d). According to Eq. (1), both factors increase the

154 LED of Mo-PtNi over PtNi. As the measured and the ML-identified ORR activity of Mo-

155 PtNi are higher than those of PtNi (Fig. 3a), our observations indicate that the average

156 catalytic activity of the Mo-PtNi and PtNi nanocatalysts is situated on the left-side of the

157 peak of the volcano (Fig. 3j), which can explain previous experimental results that a larger

158 concentration of Co or Ni in Pt-alloy nanocatalysts increases the ORR activity[31,32].

159 Although we focused on PtNi and Mo-PtNi nanoparticles in this study, our approach to

160 constructing the LED is applicable to other nanocatalysts.

161   In conclusion, we determined the 3D local atomic structure and chemical

162 composition of PtNi and Mo-PtNi nanocatalysts each comprising a few thousands of

163 atoms. We measured the facets, surface concaveness, structural and chemical

164 order/disorder, CN, and bond lengths with high precision. From the experimentally

165 measured 3D atomic coordinates, we used a DFT-trained ML method to identify the

166 active sites of the 11 nanocatalysts, which were validated by electrochemical

167 measurements. By performing a comprehensive analysis of the structure-activity

168 relationship, we derived the LED to quantitatively characterize the ORR activity of the

169 nanocatalysts based on the surface, subsurface atomic structure and chemical

170 composition. We found that the nearest-neighbour surface Pt atoms, the average Pt-Pt

171 bond length and the generalized CN for Ni neighbours are the most relevant parameters

172 for the ORR activity. The optimal reactivity is achieved with the right balance between

173 the ligand and strain effects, with subsurface Ni ligands behaving differently from surface

174 ones. We expect that this work paves the way to measure the 3D local atomic positions,

175 chemical species and surface composition of a wide range of nanocatalysts for various

176 (electro)chemical reactions and to correlate the 3D atomic structure with the catalytic

177 activity at the single-atom level.

287 plot (red dashed line) obtained by fitting the LED with the ML-identified activity of all

288 the surface Pt sites (blue dots), where the peak is at LED = 9.7. **k**, **l**, The LED-based

289 activity maps of the PtNi and Mo-PtNi nanocatalysts (particles 1 and 4, respectively),

290 which are in good agreement with the ML-identified activity maps (**b** and **c**).

291 **METHODS**

292 **Chemicals and materials**

293 Platinum(II) acetylacetonate [$Pt(acac)_2$], nickel(II) acetate tetrahydrate [$Ni(ac)_2 \cdot 4H_2O$], benzyl

294 acid (BA) were purchased from Sigma Aldrich. Molybdenum hexacarbonyl ($Mo(CO)_6$), carbon

295 nanotube (CNT) was purchased from Alfa Aesar. N, N-Dimethylformamide (DMF), acetone,

296 isopropanol were purchased from Fisher Scientific. Ethanol was purchased from Decon Labs, Inc.

297 Vulcan XC-72 carbon black (particle size ~50 nm) was from Cabot Corporation. Water used was

298 Ultrapure Millipore (18.2 MΩ·cm).

299 **Sample preparation**

300 *Synthesis of Mo-PtNi/C*. Vulcan XC-72 carbon black is pre-treated in Argon (80% in volume) and

301 Hydrogen (20% in volume) mixture at 400 C for 4 hours. 80 mg pre-treated Vulcan XC-72 carbon

302 black was dispersed in 60 mL N,N-dimethylformamide (DMF) under ultrasonication for 30

303 minutes in a 325 mL pressure bottle. Then 64 mg platinum(II) acetylacetonate [$Pt(acac)_2$], 32 mg

304 nickel(II) acetate tetrahydrate [$Ni(ac)_2 \cdot 4H_2O$], and 520 mg benzoic acid were dissolved in 10 mL

305 DMF and were also added into the 325 mL pressure bottle with carbon black dispersion. After

306 ultrasonication for 5 mins, the pressure bottle with well mixed solution was directly put into 140

307 ºC oil bath and then slowly heated to 160 ºC within 2 hrs. The pressure bottle was kept at 160 ºC

308 for 12 hrs. After 12 hours, 16 mg $Pt(acac)_2$, 8 mg $Ni(ac)_2 \cdot 4H_2O$, 3.2 mg molybdenum(0)

309 hexacarbonyl [$Mo(CO)_6$] were added into the pressure bottle. Then the pressure bottle was kept

310 in 160 ºC oil bath for 48 hrs. After reaction finished, the catalysts were collected by centrifugation,

311 then dispersed and washed with isopropanol and acetone mixture. Then the catalysts were dried

312 in vacuum at room temperature and ready for characterization and electrochemistry test.

313 *Synthesis of PtNi/C*. The preparation of procedure is same as Mo-PtNi/C noted above except

314 without adding $Mo(CO)_6$.

315 *Synthesis of Mo-PtNi/CNT.* The preparation procedure is same as Mo-PtNi/C noted above except

316 replacing treated Vulcan XC-72 with CNT.

317 *Synthesis of PtNi/CNT.* The preparation procedure is same as Mo-PtNi/CNT except without

318 adding Mo(CO)$_6$.

Electrochemical measurements and analysis

319

320 A typical catalyst ink was prepared by mixing 2.8 mg of catalyst powder (Mo-PtNi/C, PtNi/C)

321 with 2 mL of ethanol solution containing 16 µL of Nafion (5 wt%) with 5 min ultrasonication

322 time. Then, 10 µL of catalyst ink was dropped onto a 5 mm diameter glassy-carbon electrode

323 (Pine Research Instrumentation). Estimation of Pt loading is based on overall Pt ratio within

324 catalyst determined by ICP-AES. The ink was dried under an infrared lamp; then the electrode

325 was ready for electrochemical test.

326   A three-electrode cell was used to carry out the electrochemical measurements. The

327 working electrode was a catalyst coated glassy carbon electrode. A Ag/AgCl electrode was used

328 as the reference electrode. A Pt wire with a diameter of 0.05 cm and a length of 23 cm was used

329 as the counter electrode. The geometric exposed surface area of the counter electrode (A_{ce}) is

330 around 3.6 cm^2, which is more than 18 times that of working electrode (A_{we}: 0.196 cm^2). The high

331 A_{ce}/A_{we} ratio was chosen to eliminate the Pt dissolution at counter electrode. The activation

332 procedure was associated with cyclic voltammetry (CV) process, which was conducted in a N$_2$

333 saturated 0.1 M HClO$_4$ solution between 0.05 to 1.1 V vs. reversible hydrogen electrode (RHE)

334 at a sweep rate of 100 mV/s for 30 cycles. Oxygen reduction reaction (ORR) measurements were

335 conducted in an O$_2$ saturated 0.1 M HClO$_4$ solution at a sweep rate of 20 mV/s. iR compensation

336 and background subtraction were applied for ORR test curves following the protocol noted in

337 literature[33]. For the ORR measurement without activation, the prepared working electrode was

338 directly subjected to ORR test in the oxygen saturated electrolyte without being activated at

339 nitrogen saturated electrolyte via CV scan.

340   The specific activity (SA) is defined as the estimated kinetic current (at 0.9 V vs. RHE)

341 divide by the measured active surface area. The mass activity (MA) is the estimated kinetic current

342 (at 0.9 V vs. RHE) divided by the total Pt mass loaded on the working electrode. The

343 electrochemically active surface area (ECSA) refers to the measured active surface area

344 normalized by the total Pt mass loaded on the working electrode.

Data acquisition

345

346 The PtNi and Mo-PtNi nanoparticles were deposited on to 5-nm-thick silicon nitride membranes

347 annealed at 520 °C for 9 minutes in vacuum. A set of tomographic tilt series were acquired from

348 several nanoparticles using the TEAM I microscope. Images were collected at 300 kV in ADF-

349   STEM mode (Supplementary Table 1). To minimize sample drift, three to five images per angle

350   were measured with 3 µs dwell time. To ensure that no structural changes were observed during

351   the data acquisition, for each nanoparticle, we took the same projection images at zero degree

352   before, during, and after the acquisition of each tilt series. 9 PtNi and 8 Mo-PtNi nanoparticles

353   were measured in this work. The total electron dose of each tilt series for all the nanoparticles

354   were estimated to be between 7.4×10^5 e$^-$/Å^2 and 8.5×10^5 e$^-$/Å^2 (Supplementary Table 1).

355   **Image pre-processing**

356   The image pre-processing consists of the following three steps.

357   i) *Image registration and drift correction.* We acquired three to five ADF-STEM images at every

358   angle of each tilt series. The images at each angle were registered by cross-correlation. Using first

359   image as a reference, we scanned a cropped region of the subsequent images with a sub-pixel step

360   size and found the drift for every image. After drift correction, we averaged all the images at each

361   angle.

362   ii) *Image denoising.* The experimental ADF-STEM images have mixed Poisson and Gaussian

363   noise. A generalized denoising algorithm, termed block-matching and 3D filtering (BM3D), was

364   used to denoise each averaged image[34]. The robustness of BM3D on the AET data have been

365   proven in our previous studies[28,35,36].

366   iii) *Image alignment and background subtraction.* The denoised images of each tilt series were

367   aligned by the centre of mass and common line method as described elsewhere[37]. After alignment,

368   a 2D mask was calculated by the Otsu threshold in MATLAB for each image to match the shape

369   of the nanoparticle. The background was estimated by the discrete Laplacian function in

370   MATLAB. After background subtraction, all the images of each tilt series were re-aligned by the

371   centre of mass and common line to further reduce the error.

372   **3D image reconstruction and refinement**

373   After image pre-processing, each tilt series was reconstructed by an iterative algorithm, termed

374   REal Space Iterative REconstruction (RESIRE)[38]. From the experimental images, RESIRE

375   minimized the L_2-norm error metric using gradient descent. The jth iteration of the algorithm

376   consists of the following steps. RESIRE computed a set of images from the 3D object of the (j-

377   1)th iteration. The difference between the computed and corresponding experimental images was

378   calculated, from which an error metric was defined to monitor the convergence of the algorithm.

379   The difference was back projected to real space, yielding the gradient of the 3D reconstruction.

380   The 3D reconstruction of the jth iteration was updated by combining the gradient with the

381   reconstruction of the (j-1)th iteration, where positivity was enforced as constrains. As a general

382   algorithm, RESIRE is not sensitive to the initial input. After 200 iterations, a preliminary 3D

383 reconstruction was computed. Based on the preliminary 3D reconstruction, angular refinement

384 and spatial alignment were performed and background subtraction was re-evaluated. After these

385 refinement procedures, a final 3D reconstruction was obtained by running 200 iterations of

386 RESIRE.

387 **Determination of 3D atomic coordinates and chemical species**

388 To increase the precision of atom tracing, we up-sampled each 3D reconstruction by a factor of

389 three using spline interpolation, from which all the local maxima were identified. Starting from

390 the highest intensity, we fit each local maximum of a 9×9×9 voxel volume (1.4×1.4×1.4 Å^3) by a

391 3D polynomial method to locate its centre position[35]. Each fitted local maximum was considered

392 as a potential atom only when its distance from the existing potential atoms is larger than 2 Å.

393 After going through all the local maxima, we obtained a list of potential atoms. For every potential

394 atom, the integrated intensity of the 9×9×9 voxel volume around the centre position was

395 calculated. A K-mean clustering method was used to classify the non-atoms, Pt and Ni atoms[35].

396 Due to a very small fraction (~0.4%) of Mo atoms in the Mo-PtNi nanoparticles, AET is currently

397 not sensitive enough to distinguish them from Pt or Ni atoms. After excluding the non-atoms and

398 manually checking all the atoms, we obtained an initial 3D atomic model for each 3D

399 reconstruction.

400   Due to the missing wedge problem[23], we used local re-classification to reduce the effect

401 of the intensity variation in different regions of each 3D reconstruction[35]. At each atomic position,

402 we cropped a 7-Å radius sphere and calculated the mean integrated intensity for the Pt or Ni atom

403 inside the sphere. We then re-classified each atom in the sphere based on the difference between

404 its integrated intensity and the mean value of the Pt or Ni atom. The procedure was repeated until

405 there was no further change.

406   The electron energy loss spectroscopy maps of the nanoparticles show that there are

407 individual Ni atoms distributed around each nanoparticle (Supplementary Fig. 2). To evaluate the

408 effect of the surrounding Ni atoms on the 3D reconstruction, we simulated a PtNi atomic model

409 in an environment with individual Ni atoms, which used the experimentally determined 3D atomic

410 distribution for the Pt and Ni atom. After calculating projection images at different tilt angles

411 from the model, we performed image pre-processing, conducted the 3D reconstruction, traced the

412 atoms, classified the atomic species and obtained a new 3D atomic model (Supplementary Fig.

413 8). We observed that there is a layer of ghost atoms surrounding the 3D atomic model, which is

414 due to the surrounding Ni atoms around each nanoparticle (Supplementary Fig. 8d and e). Based

415 on this result, a layer of ghost atoms was removed from the experimental 3D atomic model of

416 each nanoparticle.

417 **X-ray absorption spectroscopy (XAS) data collection and analysis**

418 XAS experiments were conducted on the dry powders of the nanocatalysts studied in this work at

419 the beamline ISS 8-ID in National Synchrotron Light Source II (NSLS) (Brookhaven National

420 Laboratory, NY. Full range Pt L_3-edge and Ni K-edge spectra were collected on the same

421 electrode in transmission mode at the Pt L_3-edge, and/or Ni K-edge, with a Pt or Ni reference foil

422 positioned between I2 and I3 as a reference. Typical experimental procedures were utilized with

423 details provided in our previous work[39]. The data were processed and fitted using the Ifeffit−based

424 Athena[40] and Artemis[41] programs. Scans were calibrated, aligned and normalized with

425 background removed using the IFEFFIT suite[42]. The $\chi(R)$ were modelled using single scattering

426 paths calculated by FEFF6[43].

427 The Pt-Pt bond lengths of nanocatalysts were obtained by the extended x-ray absorption

428 fine structure (EXAFS) fitting. The average first-shell Pt-Pt bond lengths were determined by

429 fitting the EXAFS spectra of dry powders at the Pt L_3 and Ni K-edge simultaneously. S_0^2 was

430 fixed at 0.84 and 0.68 for Pt and Ni, respectively as obtained by fitting the reference foils. Fits

431 were done in R-space, $k^{1,2,3}$ weighting. $1.2 < R < 3.1$ Å and $\Delta k = 3.08 - 13.39$ Å^{-1} were used for

432 fitting the Pt L_3-edge data, and $1.3 < R < 3.1$ Å and $\Delta k = 2.56 - 11.40$ Å^{-1} were used for fitting

433 the Ni K-edge data. The fitting results of the E_0 at the Pt L_3 and Ni K edges are 8±2 eV and -6±1

434 eV, respectively. The EXAFS fit Pt-Pt bond lengths were used to calibrate the voxel size of the

435 AET experiment.

436 **Calculation of the coordination number, facet orientation and surface concaveness**

437 We used custom MATLAB scripts to measure the CN, facet orientation and surface concaveness

438 for all the atomic sites. We defined the nearest-neighbour distance by fitting the valley of the first

439 and second peak of the pair distribution function for each nanocatalyst. The CN was obtained by

440 counting the number of the nearest-neighbour sites within the cutoff distance. Each atom was

441 classified as a surface site if CN < 12 and as an internal site if CN = 12. To find the facet

442 orientation, we derived a density matrix for each nanocatalyst by convolving the atomic structure

443 with a 3D Gaussian function ($\sigma = 4$ Å). For each surface site, a normal vector was calculated by

444 computing the gradient of the density matrix at that site. By comparing the normal vectors to the

445 crystallographic directions, we determined the facet orientation of the nanocatalyst. To quantify

446 the surface concaveness, we estimated the surface curvature for all surface sites by using a

447 procedure published elsewhere[44].

448 **The normalized local bond orientational order (BOO) parameter**

449 From the 3D atomic model of each nanoparticle, we calculated the local BOO parameters (Q_4 and

450 Q_6), which are described elsewhere[28,45]. The Q_4 and Q_6 order parameters were computed up to the

451   second shell with a shell radius of 3.5 Å. We then defined the normalized local BOO parameter

452   as $\sqrt{Q_4{}^2 + Q_6{}^2}/\sqrt{Q_{4\,\text{fcc}}^2 + Q_{6\,\text{fcc}}^2}$, where $Q_{4\,\text{fcc}}$ and $Q_{6\,\text{fcc}}$ are the Q_4 and Q_6 values of a perfect

453   fcc lattice. The normalized BOO parameter is between 0 and 1, where 0 means $Q_4 = Q_6 = 0$, and

454   1 represents a perfect fcc crystal structure.

455   **The chemical order parameter**

456   The chemical order of each nanoparticle was calculated by the pair-wise multicomponent short-

457   range order parameter[46],

458    $$\alpha_{ij} = \frac{p_{ij} - C_j}{\delta_{ij} - C_j} \qquad (2)$$

459   where p_{ij} is the probability of finding a j-type atom around an i-type atom in the first nearest

460   neighbour shell. C_j is the concentration of j-type atoms in the nanoparticle and δ_{ij} is the

461   Kronecker delta function. Since there are primarily Pt and Ni atoms in the nanoparticles, all the

462   α_{ij} parameters are correlated. In this study, we chose α_{12} to represent the chemical order

463   parameter. A positive and a negative α_{12} represent segregation and alloying, respectively.

464   **DFT calculations**

465   The DFT calculations were conducted by the VASP package[47-50]. The core electrons were

466   described by the projector-augmented-wave method[51] and the valence states by plane waves up

467   to 400eV. The exchange-correlation interaction of electrons was defined by the Perdew-Bruke-

468   Ernzerhof functional[52]. Spin-polarized calculations were used throughout this manuscript for the

469   PtNi nanocatalysts. The Brillouin zone was sampled by a uniform density of 0.19 Å^{-1} in each

470   reciprocal direction. For isolated clusters, only Γ point was considered. A database of OH

471   adsorption energies on the surface Pt sites of the PtNi model catalysts were computed by DFT

472   (Supplementary Fig. 10). The database includes diverse 3D atomic models consisting of

473   nanoclusters and slabs. The nanoclusters of different sizes were built from truncated octahedra,

474   and the slab models were created from closed-packing surfaces, including fcc(110) surfaces,

475   fcc(100) surfaces and concave shapes similar to these published elsewhere[11]. Ni atoms were

476   introduced by randomly replacing the Pt atoms. The Ni concentration ranges from 0 to 69.6% in

477   the 3D atomic models and from 0 to 83.9% in the local environment (defined as the atoms within

478   the 6.5 Å radius from an adsorption site). Different lattice constants were used to represent tensile

479   and compressive strain. In total, the OH was adsorbed on 207 Pt sites with different Pt CNs, Ni

480   concentration and local environments. The OH binding energy on the Pt sites (BE_{OH}) was

481   computed by,

482    $$BE_{OH} = E_{OH@Model} - E_{OH} - E_{Model} \qquad (3)$$

483   where $E_{OH@Model}$ is the total electronic energy of the optimized OH adsorbed structure, E_{OH} is

484   the electronic energy of the OH radical in the gas phase, and E_{Model} is the energy of optimized

485   model without OH adsorption.

Evaluation of the OH binding energy by DFT-trained ML

487   To evaluate BE_{OH} for all the surface Pt sites, we used a ML method - the Gaussian process

488   regression (GPR)[53]. The ML-GPR method was trained by the DFT-calculated BE_{OH}, and the local

489   atomic environment of the Pt sites was characterized by the smooth overlap of atomic positions

490   (SOAP) approach[54,55]. The cutoff radius of 6.5 Å was selected in SOAP, which was later validated

491   by the accurate prediction of the ML-GPR method (Supplementary Fig. 11). The GPR was

492   implemented by the Python-scikit package[56]. The kernel function is defined as normalized

493   polynomial kernel of the partial power spectrum,

$$K(\mathbf{d}_1, \mathbf{d}_2) = \left(\frac{\mathbf{d}_1^T \mathbf{d}_2}{\sqrt{\mathbf{d}_1^T \mathbf{d}_1 \mathbf{d}_2^T \mathbf{d}_2}} \right)^{\zeta} \quad (4)$$

495   Where $K(\mathbf{d}_1, \mathbf{d}_2)$ is the kernel function between SOAP descriptors $\mathbf{d}_1$ and $\mathbf{d}_2$, and ζ is a

496   hyperparameter. In this study, we chose $\zeta = 4$ by balancing the accuracy and transferability. We

497   trained the GPR by randomly choosing 134 atomic models and then used the ML method to

498   predict the BE_{OH} of the remaining 73 atomic models. The RMSE is 0.05 and 0.07 eV per site for

499   the training and test set, respectively (Supplementary Fig. 11). The small REMS values indicate

500   the robustness of the ML method. After validating DFT-trained ML, we applied it to evaluate the

501   BE_{OH} of the surface Pt sites of the 7 PtNi and 4 Mo-Pt/Ni nanocatalysts.

Estimation of the ORR activity based on the OH binding energy

503   From the ML-identified BE_{OH}, we estimated the ORR activity of each surface Pt site by

504   calculating ΔBE_{OH},

$$\Delta BE_{OH} = BE_{OH} - BE_{OH,Pt(111)} \quad (5)$$

506   where $BE_{OH,Pt(111)}$ is the OH binding energy of Pt(111). As the ORR activity and ΔBE_{OH} are

507   related to each other by the volcano-type plot[29,57,58], we evaluated the current density of the ORR

508   oxygen using formulas published elsewhere[57]. On the left side of the volcano plot, we computed

509   the current density of the ORR for the ith surface Pt site (j_i) by,

$$kT \ln \left(\frac{j_i}{j_{Pt(111)}} \right) = \Delta BE_{OH,i} \quad (6)$$

511   where k is the Boltzmann constant, T the temperature, $j_{Pt(111)}$ the current density of the ORR for

512   Pt(111), and $\Delta BE_{OH,i}$ the OH binding energy difference (Eq. (5)) for the ith surface Pt site. We

513   computed the current density of the ORR on the right side of the volcano plot by,

$$kT\ln\left(\frac{j_k}{j_{Pt(111)}}\right) = 0.26 - 0.97 \cdot \Delta BE_{OH,k} \qquad (7)$$

where k represents the kth surface Pt site. Based on Eqs. (6) and (7), the current density of any surface Pt site is obtained by,

$$j = \min(j_i, j_k) . \qquad (8)$$

Figure 3b, c, Supplementary Fig. 12 and Video 2 shows the ML-identified activity of all the surface Pt sites (blue dots) for the 7 PtNi and 4 Mo-Pt/Ni nanocatalysts. We observed that the ORR activity of the various surface Pt atoms differs by several orders of magnitude. The average activity of these nanocatalysts is in good agreement with the electrochemically measured activity (Fig. 3k, l, Supplementary Fig. 13 and Video 2).

Derivation of the LED equation

We derived the LED by fitting a large number of experimentally measured structural and chemical properties to the ΔBE_{OH} of the surface Pt sites of the 7 PtNi and 4 Mo-Pt/Ni nanocatalysts. The fitting variables include the CN, the surface CN, the sub-surface CN, the average Pt-Pt bond length around each Pt site ($\bar{d}_{Pt}$), the structure/chemical order parameter, the nearest-neighbor Pt and Ni atoms of each surface Pt atom (NN^{Pt} and NN^{Ni}), the generalized CN ($\overline{CN}$), the element-based $\overline{CN}$ ($\overline{CN}^{Pt}$ and $\overline{CN}^{Ni}$), etc. We examined the 2, 3 and 4 variable LED equations to minimize the RMSE by,

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}\left(\Delta BE_{OH,i}^{ML} - \Delta BE_{OH,i}^{Cal}\right)^2}{N}} \qquad (9)$$

where $\Delta BE_{OH,i}^{ML}$ is the ΔBE_{OH} of the ith surface Pt site obtained by ML, N is the total number of the surface Pt sites, and $\Delta BE_{OH,i}^{Cal} = E_1 * LED - E_0$ with E_1 and E_0 are two fitting constants. For the 2 variable LED equation, we examined $LED = a_1 x_1 + a_2 x_2$, where a_1 and a_2 are two fitting constants, x_1 and x_2 are two fitting variables. We obtained the smallest RMSE value of 0.117 eV by choosing $x_1 = CN$ and $x_2 = e^{-\bar{d}_{Pt}}$. For the 3-variable LED equation, we found that $LED = a_1 x_1 * x_2 + a_2 x_3$ produces the smallest RMSE value of 0.104 eV with $x_1 = NN^{Pt}$, $x_2 = e^{-\bar{d}_{Pt}}$ and $x_3 = \overline{CN}^{Ni}$ (Supplementary Table 2). For the 4-variable LED equation, we examined $LED = a_1 x_1 * x_2 + a_2 x_3 * x_4$ and $LED = a_1 x_1 * x_2 + a_2 x_3 + a_3 x_4$. After testing all the fitting variables, we derived an optimized equation, $LED = a_1 x_1 * x_2 + a_2 x_3$, with the RMSE of 0.104 eV. We revised the equation to be $LED = NN^{Pt} \cdot e^{-a_1 \cdot \varepsilon} + a_2 \cdot \overline{CN}^{Ni}$, where $\varepsilon = \frac{\bar{d}_{Pt} - d_0}{d_0}$ and $d_0 = 2.75$ Å is the Pt-Pt bond length of the Pt nanoparticles. The revision only changed the fitting constants, but not the RMSE. With this LED equation, we have $a_1 = 1.985$, $a_2 = 1.075$, $E_1 = 0.189$, $E_0 = 0.1703$, and RMSE = 0.104 eV.

Data availability

All the raw and processed experimental data will be posted on https://github.com, which can be freely downloaded, immediately after the paper is published. The 3D atomic coordinates of PtNi and Mo-PtNi nanoparticles will be deposited in the Materials Data Bank (www.materialsdatabank.org) immediately after the paper is published.

Code availability

All the MATLAB source codes for the 3D image reconstruction, atom tracing, refinement and data analysis of this work will be posted on https://github.com, immediately after the paper is published.

625   **Author contributions** J.M. directed the project; Z.Z., Y.L. and Y.H. synthesized the samples and

626   performed the ORR test; J.Z., P.E., J.C. and J.M. discussed and/or conducted the AET

627   experiments; Q.J. and Q.S. did the XAS experiment; Yao Yang, Yongsoo Yang, Y. Yuan and

628   J.M. performed 3D image reconstruction, atom tracing and classification; G.S., Z.Y., and P.S.

629   carried out the DFT calculations and implemented the ML method with input from Yao Yang,

630   C.O. and J.M.; Yao Yang, J.Z., Z.Z., G.S., C.O., S.M., C.Z., H.H., P.S., Y.H. and J.M. analyzed

631   and/or interpreted the results J.M., Yao Yang, S.M. Z.Z. and G.S. wrote the manuscript. All

632   authors commented on the manuscript.

633   **Competing interests** The authors declare no competing interests.
