Version of Record: A version of this preprint was published at Cardiovascular Diabetology on May 11th, 2020. See the published version at <https://doi.org/10.1186/s12933-020-01033-4>.

Abstract

Background: To assess the prognostic role of coronary collaterals in patients with type 2 diabetes mellitus (T2DM) after successful percutaneous coronary intervention (PCI) for chronic total occlusion (CTO).

Methods: Coronary collateralization was graded according to Rentrop scoring system in 198 type 2 diabetic patients and 335 non-diabetics with stable angina undergoing PCI for at least one CTO lesion. Left ventricular ejection fraction (LVEF) was determined and major adverse cardio-cerebral events (MACCE) were recorded during follow-up.

Results: Poor collateralization was more common in patients with T2DM than in non-diabetics (40% vs 29%, $p=0.008$). At 13.5 ± 4.1 months, the rate of composite MACCE (17.3% vs 27.6%, $p=0.034$) and repeat revascularization (15.2% vs 25.5%, $p=0.026$) was lower and the increase in LVEF (3.10 % vs 1.80%, $p=0.024$) was greater in patients with good collaterals than in those with poor collaterals for non-diabetic group, but did not differ for T2DM group (35% vs 44%; 30% vs 36%; 2.14% vs 1.65%, respectively, all $p>0.05$) except for a higher all-cause mortality in diabetic patients with poor collaterals ($p=0.034$). Multivariable Cox proportional hazards analysis showed that coronary collateralization was an independent factor for time to MACCE (HR 2.155 [95%CI 1.290-3.599, $P=0.003$]) and repeat revascularization (HR 2.326, 95%CI 1.357-3.986, $p=0.002$) in non-diabetic patients, but did not enter the model in those with T2DM.

Conclusions: T2DM is associated with reduced coronary collateralization. Successful revascularization of CTO lesions results in a mild improvement in left ventricular function, but the status of coronary collaterals has no independent effect on long-term clinical outcomes in patients with T2DM.

Background

Chronic total occlusion (CTO) occurs in 20–30% of patients with significant coronary artery disease undergoing routine coronary angiography^{1,2}. Both randomized trials and observational studies have demonstrated that successful revascularization of chronic totally occluded lesions accomplished by percutaneous coronary intervention (PCI) or coronary artery bypass grafting is associated with a number of clinical benefits, such as anginal symptom relief, improved quality of life and ventricular function, and decreased mortality when compared to CTO patients whose recanalization was failed or those who received optimal medical treatment only^{3–6}. Therefore, revascularization is recommended as an initial therapeutic modality in patients with CTO by current guidelines⁷. Recently, with the improvement in dedicated devices, technical strategies and interventional skills, the overall success rate of PCI for CTO (CTO-PCI) has been dramatically increased⁸.

Diabetes mellitus is regarded as a coronary heart disease risk equivalent and an important factor when planning treatment strategies for coronary artery disease as well as evaluating clinical outcomes after

PCI^{9,10}. Patients with type 2 diabetes mellitus (T2DM) often have an elevated incidence of CTO (approximately 30%-40% in the registry)^{11,12}. In the setting of complete coronary obstruction, blood supply to the distal myocardium is solely from collateral vessels. The formation and maturation of coronary collateral circulation is an adaptive physiologic response, and well-formed collaterals may minimize infarcted area and improve ventricular function and survival compared with patients lacking a well-developed collateral network^{13,14}. However, the prognostic role of collaterals in patients with coronary artery disease remains controversial. In myocardial infarction patients with acute coronary occlusion, previous studies yielded mixed results with some showing improved clinical outcomes in patients with angiographic evidence of collaterals¹⁵⁻¹⁷ and others revealing either no difference¹⁸⁻²⁰ or worse outcomes²¹. In stable coronary artery disease patients with CTO, while T2DM is strongly associated with reduced coronary collateral formation²²⁻²⁴, few published studies have focused on the impact of coronary collaterals on clinical prognosis, especially for those with T2DM after CTO-PCI⁶.

Therefore, we conducted a prospective, observational study to examine the effect of coronary collateralization on long-term clinical outcomes in type 2 diabetic and non-diabetic patients with stable coronary artery disease after successful CTO-PCI.

Methods

The protocol was approved by the Shanghai Jiao Tong University ethic committee and conducted in accordance with the Declaration of Helsinki. All patients gave written informed consent.

Study population

A total of 779 consecutive patients with stable angina who were attempted to undergo CTO-PCI of at least one major epicardial coronary artery between January 2016 and December 2018 were recruited from the database of Shanghai Rui Jin Hospital PCI Outcome Program. This program utilizes clinical and angiographic information for various cardiovascular diseases to estimate risk-adjusted outcomes. Data on demographics, clinical and angiographic features, left ventricular function determined by two-dimensional echocardiography according to modified Simpson's rule, and in-hospital management were collected retrospectively, whereas clinical outcomes during follow-up were identified prospectively.

For the purpose of this study, 98 patients were excluded because of a history of coronary artery bypass grafting (n = 56), renal failure requiring hemodialysis (n = 12), chronic heart failure with NYHA class III or IV (n = 17), pulmonary heart disease (n = 6) and malignant tumor or immune system disorders (n = 7), as these conditions could influence collateral formation. Patients with type 1 diabetes (n = 6) were excluded by measurement of C-peptide level. In the 675 eligible patients, CTO-PCI was successful in 561 patients (83%). The main causes for failed procedure included impossibility of wire (n=85) or balloon (n=15) to cross the occluded segment and major complications (coronary dissection: n=9; coronary perforation:

n=5). We also excluded additional 28 (5%) patients who were lost to follow up. Thus, the remaining 533 patients were enrolled in the final analyses. Among them, 198 patients (37%) had T2DM and 335 (63%) were non-diabetics (**Figure 1**).

CTO was defined as those occluded arteries with a documented duration of occlusion of at least 3 months with absolutely no flow through the lesion (TIMI grade 0) ²⁵. Estimation of the duration of coronary occlusion was based on the first onset of an abrupt worsening of existing angina, a history of myocardial infarction in the target vessel territory, or information obtained from a previous angiogram. Stable angina was diagnosed according to the criteria recommended by the American College of Cardiology/ American Heart Association ²⁶. T2DM was defined as a fasting glucose level >126 mg/ dL or glycated hemoglobin A1c concentration greater than 6.5% assessed at least once, or the current use of oral hypoglycemic agents or insulin ²⁷.

Coronary intervention procedure

Coronary angiography and intervention were performed with standard techniques using 6F or 7F guiding catheters via the radial or femoral approach and drug-eluting stent implantation as the default strategy (>95% cases). Before the procedure, all patients received loading dose of aspirin (300mg/d) and clopidogrel (300mg) or ticagrelor (180mg). During the procedure, an intravenous bolus of heparin (70-100 IU/kg) was given, but the use of glycoprotein IIb/IIIa inhibitors was at the operator's discretion. CTO-PCI was performed using contemporary techniques such as bilateral injection; specialized hydrophilic, tapered tip, and stiff wires; parallel wires; microcatheters; and retrograde approach. The choice of guidewires, balloons, and drug-eluting stent type was left to the discretion of the operators. After the procedure, clopidogrel (75mg/day) or ticagrelor (90mg, twice daily) was prescribed for at least 12 months, and aspirin (100mg/day) was continued indefinitely. After discharge, all patients were encouraged to take guideline- recommended medications including statins, angiotensin-converting enzyme inhibitors and β -blockers unless contraindicated, and to receive repeat coronary angiography at 12 months during follow-up.

Technical success was defined as a residual stenosis of < 20% and restoration of TIMI grade 3 flow. Procedural success was defined as technical success without death, myocardial infarction, or emergency coronary bypass grafting. Complete revascularization was defined as restoration of TIMI grade 3 flow with residual stenosis < 20% in all three major coronary arteries and their branches (diameter $\geq$ 2.0mm).

Coronary collateral scoring

The degree of coronary collaterals supplying the distal aspect of a total occlusion from the contra-lateral vessel was graded according to Rentrop classification: 0 = no visible filling of any collateral channel; 1 =

filling of side branches of the artery to be perfused by collateral vessels without visualization of epicardial segment; 2 = partially filling of the epicardial artery by collateral vessels; 3 = complete filling of the epicardial artery by collateral vessels²⁸. Patients were categorized into poor (grade 0 or 1) or good (grade 2 or 3) coronary collateralization group. All angiograms were viewed by the two observers blinded to the other observers' findings, and the agreement of the assessment of coronary artery disease severity and collateral classification between the two observers was 98% and 97%, respectively²⁹. Any difference in interpretation was resolved by a third reviewer. For those with more than one total coronary occlusion, the vessel with the highest collateral grade was chosen for analysis.

Study endpoints

The primary study endpoint was the occurrence of composite major adverse cardio-cerebral events (MACCE) during follow-up, including all-cause death, cardiac death, non-fatal myocardial infarction, repeat revascularization, and non-fatal stroke. All-cause death was defined as any post-procedure death, and the cause was considered cardiac unless a definite non-cardiac cause was established. Myocardial infarction was defined as recurrent symptoms with new electrocardiographic changes compatible with myocardial infarction or cardiac marker level at least twice the upper limit of normal. Repeat revascularization was defined as any revascularization of either the target or non-target vessels with PCI or coronary artery bypass grafting. In-stent restenosis was defined as recurrence of lumen diameter reduction >50% within the stent or 5mm proximal or distal segment adjacent to the stent at follow-up angiography³⁰. Atherosclerotic lesion progression was diagnosed if one of the following criteria was met: (1) $\geq 20\%$ diameter reduction of a pre-existing stenosis >50%; (2) $\geq 30\%$ diameter reduction of a stenosis <50%; (3) progression of any stenosis to total occlusion, or (4) development of a new stenosis >50% in a previously normal segment³¹. The secondary study endpoint was the change in left ventricular ejection fraction (LVEF) determined by two-dimensional echocardiography using modified Simpson's method.

Statistical analysis

Continuous variables are expressed as mean $\pm$ standard deviation (SD) and categorical data as percentages. Two-side Student's t test was used to compare continuous variables, and Pearson chi-square statistics was used to compare categorical values. The rate of composite MACCE and repeat revascularization were compared by calculating risk ratio with 95% confidence intervals (CIs). Cumulative rate of individual and composite outcomes was estimated using the Kaplan-Meier methods and compared with the log-rank test. Multivariable models were built by stepwise variable selection, and covariates with $p < 0.10$ level on univariable analysis or clinically relevant were considered candidate variables. Adjusted hazard ratios were compared by Cox regression based on: age, gender, risk factors for coronary artery disease (current smoking, hypertension, hypercholesterolemia, and diabetes), extent of coronary artery disease (categorized as 1-, 2-, or 3-vessel disease), collateral classification, glomerular

filtration rate, pre-procedural LVEF, and completeness of revascularization. A probability level of $p < 0.05$ was considered significant. All analyses were performed using the software package SPSS, version 13 (SPSS Inc, Chicago, IL, USA).

Results

Clinical and angiographic features

Compared with non-diabetic patients, those with T2DM were more males in gender distribution, and had higher percentage of hypertension, multivessel disease and poorer coronary collaterals, and lower LVEF (**Table 1**). Univariable regression analysis showed that presence of T2DM was the only determinant of poor coronary collateralization ($r = 0.114$, $p = 0.008$).

During PCI procedure, a total of 560 CTO lesions were successfully recanalized with drug-eluting stent implantation. There were no differences in location of CTO, stent number for CTO lesion and the rate of complete revascularization between patients with and without T2DM except that those with T2DM had higher proportion of multivessel disease ($p = 0.006$) (**Table 1**).

Long-term clinical outcomes

During a mean of 13.5 ± 4.1 months of follow-up, 8 patients died (1.5%); 5 of them had cardiac death (good collaterals in 1 patient [0.3%] and poor collaterals in 4 patients [2.2%], $p = 0.026$). and other 3 died of respiratory failure due to pulmonary infection ($n = 1$) or cerebrovascular accidents ($n = 2$). Repeat revascularization was performed in 125 patients (23.5%) because of in-stent restenosis or new lesions and disease progression. Overall, the rate of composite MACCE (38% vs 19.4%, $p < 0.001$) and repeat revascularization (32% vs 18.2%, $p < 0.001$) was higher in type 2 diabetic patients compared to non-diabetics.

For non-diabetic patients, poor collateralization was associated with more in-stent restenosis (14.3% vs 6.3%, $p = 0.018$) and repeat revascularization (25.5% vs 15.2%, $p = 0.026$), leading to a higher rate of composite MACCE (27.6% vs 17.3%, $p = 0.034$). In contrast, for type 2 diabetic patients, the rate of composite MACCE, in-stent restenosis and repeat revascularization did not differ irrespective of collateral status, except for a higher all-cause mortality in those with poor collateralization ($p = 0.034$) (**Table 2**). Kaplan-Meier curve analysis revealed a clear difference in percent event-free from MACCE or repeat revascularization according to the presence or absence of T2DM or Rentrop class of coronary collateralization (**Figure 2**).

Left ventricular function

Baseline LVEF was higher in patients with good collaterals than that in those with poor collateral for non-diabetics but was similar between type 2 diabetic patients with good and poor collaterals. Successful CTO-PCI was associated with a mild increase in LVEF irrespective of the status of diabetes and coronary collateralization (all $p < 0.001$). The degree of increase in LVEF was significantly greater in patients with good collaterals than in those with poor collaterals for non-diabetic group (3.10% vs 1.80%, $p = 0.024$) but did not differ between patients with good and poor collaterals for T2DM group (**Table 3**).

Multivariate analysis

Multivariable Cox proportional hazards regression analysis revealed that T2DM but not the status of coronary collateralization was independent factors for time to MACCE (HR 1.633 [95%CI 1.157-2.304, $P = 0.005$) and repeat revascularization (HR 1.515, 95%CI 1.046-2.192, $p = 0.028$). Further analysis showed that the status of coronary collateralization was an independent factor for time to MACCE (HR 2.155 [95%CI 1.290-3.599, $P = 0.003$) and repeat revascularization (HR 2.326, 95%CI 1.357-3.986, $p = 0.002$) in non-diabetic patients, but it did not enter the model in those with T2DM (**Table 4**).

Discussion

The results of this prospective, observational study show that: 1) T2DM was associated with reduced coronary collateralization; 2) successful revascularization of CTO lesions slightly improved left ventricular function; 3) the status of coronary collaterals exerted an independent effect on prognosis in non-diabetic patients but not in those with T2DM.

Notably, all patients in this study were specially selected as they received successful CTO-PCI and were encouraged to take guideline-recommended medications after procedure. Our findings support the notion that T2DM represents an increased risk for CTO^{2,11,12} and is a powerful independent factor for increased cardiovascular mortality and repeat revascularization after CTO-PCI^{9,10}. Abundant evidence has demonstrated that T2DM exerts a detrimental effect on glucose and lipid metabolism and vascular endothelial function, leading to development and progression of coronary atherosclerosis and unfavorable clinical outcomes³²⁻³⁵. In this study, T2DM was the only independent risk factor for poor coronary collateralization, suggesting that presence of T2DM is correlated negatively with the development of functional collateral arteries^{22,23}, and may contribute partially to adverse prognosis of CTO patients³⁶. Although presence of a chronic totally occluded lesion has been considered as a prerequisite for spontaneous collateral recruitment, the mechanism of collateral vessel growth is complex in situations where atherosclerosis affects large conductance arteries³⁷, and even become more complicated by the presence of T2DM in which multiple biochemical and cellular components are involved^{23,38,39}.

Another finding of this study is that around one-year post successful CTO-PCI, although patients with good coronary collateralization experienced a significantly lower rate of composite MACCE and repeat revascularization compared to those with poor collateralization, and Kaplan-Meier curves revealed the cumulative survival free from repeat revascularization and MACCE was significantly different according to the Rentrop class of coronary collateralization, multivariable Cox proportional hazards regression models revealed that the status of coronary collateralization was independently associated with long-term clinical outcomes only in non-diabetic patients but not in those with T2DM. The explanation for these observations is likely to be multi-factorial. Numerous studies have shown that when the proximal part of a coronary artery is occluded, collateral circulation could, at least partially, supplies the downstream perfusion area via the arteriolar connection, thereby preventing or alleviating ischemia, and its extent is a primary determinant of the severity of myocardial damage (infarct size and/or left ventricular function) and mortality after transient or permanent coronary obstruction^{13,14}. However, blood supply of the well-developed collaterals may not fully substitute normal coronary flow^{1,40}, and thus good collateral circulation for myocardial protection is not sufficient. Importantly, good collaterals in majority of patients will be rapidly subside after successful recanalization of a CTO, as antegrade blood flow is re-established and resistance is increased in the collateral vessels^{36,40}. Kim et al found that good collateral circulation for myocardial protection only exists before recanalization forms an effective perfusion⁴¹. In addition, previous studies suggest that the occurrence of in-stent restenosis after successful CTO-PCI is not influenced by coronary collateralization³⁰ or even elevated in patients with good collaterals⁴². These could lead to a similar or increased rate of repeat revascularization and overall MACCE in patients with good collaterals after success CTO-PCI.

In this study, mean LVEF was slightly increased by 2.50% during follow-up which is lower than that previously reported (4.44%)⁴³. Nevertheless, non-diabetic patients with good collateralization had a significantly greater improvement in left ventricular function compared to those with poor collaterals. Ripley et al found that viable myocardium was present in 83% of patients with good collaterals versus 38% of those with poor collaterals⁴⁴. Likewise, Choi et al observed that increased angiographic collateral flow was associated with lower degree of late gadolinium enhancement transmuralty after CTO recanalization, in contrast, poorly collateralized myocardial segments would be less likely to recover function in comparison with well collateralized segments⁴⁵. Compared with non-diabetics, type 2 diabetic patients had lower LVEF at baseline, and the change in LVEF was smaller and did not differ after successful CTO-PCI irrespective of collateral status. These findings are consistent with previous reports that myocardial and collateral function is more severely depressed in the diabetic setting^{9,10,22,23}.

Study limitations

We recognize that there are several limitations in our study. First, a potential weakness of our study is the small sample size and heterogeneity with respect to the patient distribution. Second, the study is cross-

sectional for the point of coronary collateral and MACCE or improvement of LVEF investigation, thereby allowing us to detect association, not to formulate causal link. Third, the presence and degree of coronary collaterals were evaluated according to the Rentrop scoring system. Although this angiographic assessment of coronary collaterals is easily to be incorporated into the routine clinical practice, coronary collaterals may be more accurately assessed by collateral flow index with simultaneous measurement of aortic pressure and the distal pressure within the occluded segment of the culprit coronary artery⁴⁰. Finally, clinical follow-up was relatively short in duration, and amount of viable myocardium or ischemia was not evaluated using functional tests, thus large-scale prospective studies are required to further determine the impact of coronary collateral circulation on prognosis after successful CTO-PCI.

Conclusions

The present study suggests that presence of T2DM is associated with reduced coronary collateralization. Successful revascularization of CTO lesions results in a mild improvement in left ventricular function, but the status of coronary collaterals has no independent effect on long-term clinical outcomes in type 2 diabetic patients. These findings may provide clinical insight into the management of patients with stable coronary artery disease.

Tables

Please see the supplementary files section to access the tables.

Figures

Figure 1

Flowchart patient enrollment. CTO: chronic total occlusion; T2DM: type 2 diabetes mellitus

Figure 2

Kaplan-Meier curves. Percent event-free from MACCE and repeat revascularization in non-diabetic and type 2 diabetic patients (A and B) and in those with good and poor coronary collateral circulation (C and D). MACCE: major adverse cardio-cerebral events
