Abstract

Many new TB vaccine candidates in the development pipeline need to be studied in people with HIV. People with HIV are at high risk of developing *Mycobacterium tuberculosis* (Mtb) infection and TB disease and tend to develop less robust vaccine induced immune responses. Many questions remain unanswered regarding priority vaccine indications, clinical trial design, measures of safety, immunogenicity, and efficacy considerations for people with HIV. To address these gaps, a roadmap for developing TB vaccines for people with HIV was developed through a series of symposia that posed framing questions to a panel of international experts for discussion. Framing questions specific to people with HIV included: 1) What is the use case or rationale for developing TB vaccines?; 2) What is the landscape of TB vaccines?; 3) Which vaccine candidates should be prioritized ?; 4) What are the TB vaccine trial design considerations?; 5) What is the role of immunological correlates of protection?; and 6) What are the gaps in preclinical models for studying TB vaccines? We provide a summary of our roadmap with the intention of informing TB vaccine development and the prioritization of clinical trials for inclusion of people with HIV.

Full Text

Tuberculosis (TB), caused by *Mycobacterium tuberculosis* (Mtb), was responsible for 1.5 million deaths in 2020 and continues to pose a threat to global health, particularly to those who live in high TB burden nations. The World Health Organisation (WHO) estimated that 9.9 million people developed TB in 2020, 8% of whom were coinfecting with HIV¹. Almost 800,000 people with HIV were diagnosed with TB in 2020 leading to 214,000 deaths¹.

People with HIV have a two- to 20-fold higher risk of developing TB disease and succumbing to death compared to their uninfected counterparts¹⁻³. HIV infection results in T-cell immune dysfunction, including in the lung⁴⁻⁶. Although the risk of TB in people with HIV may be substantially reduced by antiretroviral therapy (ART) and TB preventive treatment (TPT)^{7,8}, ART does not fully reconstitute HIV-induced immune suppression, which may compromise immune-dependent clearance of TB⁹.

Purpose of TB vaccine roadmap for people with HIV

A comprehensive roadmap for TB vaccines has been recently developed, but does not specifically address TB vaccines in people with HIV¹⁰. We therefore sought to define a TB vaccine roadmap to accelerate development of TB vaccines for people with HIV highlighting the key gaps and priorities with respect to 1) basic and translational studies, 2) pre-clinical models, 3) vaccine candidate selection, and 4) clinical trial design considerations that need to be addressed (Fig. 1).

TB vaccines

Bacillus Calmette-Guérin (BCG)

BCG, a live attenuated vaccine first used in 1921, remains the only vaccine for the prevention of TB. BCG is effective in preventing severe forms of TB in children, particularly TB meningitis and miliary TB, and in 2004 the WHO recommended a single dose of BCG be given to infants at birth in high TB burden countries. In 2007, WHO provided additional guidance that HIV-infected infants and children not on ART should not be given BCG due to

an increased risk of disseminated BCG disease¹¹. More recent evidence however suggests that HIV-infected infants and children who initiate ART early prior to immunological or clinical progression have a reduced risk of developing BCG-IRIS (immune reconstitution inflammatory syndrome) regional lymphadenitis¹². The WHO SAGE Working Group on BCG vaccination in 2017 therefore recommended that BCG administration can be considered in people with HIV that are clinically well and immunologically stable, especially those living in high burden countries¹³.

TB vaccine pipeline

There are 10 vaccine candidates currently in Phase 1-Phase 3 clinical trials and several more in various stages of planning (Fig. 2)¹⁴⁻¹⁷. Vaccine candidates in development include live attenuated (n = 3), viral vector (n = 1), protein subunit (n = 4), and whole cell/inactivated (n = 2) that may be used for the prevention of infection (POI), prevention of disease (POD), prevention of recurrence (POR), and adjunctively with TB treatment (therapeutic vaccines). So far, no DNA or mRNA-based TB vaccines are being tested in humans.

TB vaccine trials in people with HIV

Justification

Due to HIV-associated immunosuppression, TB vaccines in people with HIV may have lower immunogenicity and efficacy¹⁸. People with HIV have historically been excluded from TB vaccine trials to maximize the ability to demonstrate immunogenicity and efficacy. Furthermore, there have been concerns with using live attenuated vaccines, such as BCG, in people with HIV, particularly those not on ART, due to possible dissemination of live bacteria.

In high HIV prevalence communities, modelling suggests that exclusion of people with HIV from mass POD vaccination campaigns targeting adolescents and adults reduces the ability to control TB transmission at a population level¹⁹. As people with HIV are a large subpopulation of persons at high risk of TB infection and disease, it is crucial that TB vaccine trials include people with HIV. Additional evidence is required to optimize vaccine safety, immunogenicity and efficacy in people with HIV.

Experience

To date, nine completed studies involving six TB vaccine candidates have included people with HIV: two viral vectored (MVA85A, Aeras-402), two subunit (H1:IC31, M72/AS01E), and two whole cell inactivated bacterial vaccines (RUTI, *M. obuense*)^{18,20-31}. Overall, TB vaccines in people with HIV are safe, induce cellular immunity, and have variable durability. The key findings from trials that evaluated TB vaccines in people with HIV are summarised in the **Supplementary Appendix**. Furthermore, several trials are in the planning and development stages, and a subset of these will include people with HIV (Fig. 2).

Methods

In 2019, the U.S. National Institute of Allergy and Infectious Diseases (NIAID) established a Cross-Network TB Vaccine Working Group comprised of members from the AIDS Clinical Trials Group (ACTG), HIV Vaccine Trials Network (HVTN), International Maternal Pediatric Adolescent AIDS Clinical Trials (IMPAACT) Network, and NIAID.

The Working Group was tasked to develop a roadmap to help guide the prioritization of candidate vaccines for study in people with HIV. Between January and March 2021, the Cross-Network Working Group along with NIAID convened an international panel of recognized experts in TB and HIV epidemiology, modelling, clinical care, immunology, vaccinology, ethics, community engagement, and regulatory affairs to participate in a virtually held workshop. We also invited members of the TB vaccine working groups from the three networks, opinion leaders, representatives from the global community of HIV and TB, vaccine developers, funders, and other TB research networks. Subject matter experts were identified based on review of published work as well as those known to be working in the field of TB vaccines. Organizers and panellists were tasked with generating consensus statements supporting priorities and pathways for inclusion of people with HIV in trials of novel TB vaccine candidates and strategies. Discussions were framed by six guiding questions (**Box 1**) developed a priori by the organizing members (GC, AG, JGK) with input from participating experts (see Acknowledgements). A series of presentations by subject matter experts was followed by discussion sessions based on the six framing questions developed by the symposium organizers and experts. The workshop was conducted virtually comprised of a total of six sessions (see **Supplementary Appendix** for full agenda). A written draft of the roadmap including the summary discussions of the framing questions and consensus statements was developed by a core group (GC, AG, JGK, MDM) and additional comments to the roadmap were then sought by participating subject matter experts.

Box 1. Framing Questions.

- What is the use case or rationale for developing TB vaccines for people with HIV?
- What is the landscape of TB vaccines for people with HIV?
- Which vaccine candidates should be prioritized for study in people with HIV (infants, children, adolescents, and adults)?
- What are the trial design considerations of TB vaccine trials that include people with HIV?
- What is the role of immunological correlates of protection in people with HIV?
- What are the gaps in preclinical models for studying TB vaccines in people with HIV?

Results

Framing questions and consensus statements

For each framing question, the context for each question is provided followed by the consensus statement.

1. What is the use case or rationale for developing TB vaccines for people with HIV?

Context: TB remains the leading cause of morbidity and mortality in people with HIV, and persons with advanced HIV have the highest risk for TB disease¹. Despite ART lowering viral load to undetectable levels and effective TPT reducing the risk of TB, people with HIV remain at significantly higher risk of developing TB and having poorer outcomes than the general population^{32,33}. As HIV results in innate and adaptive immune response dysfunction, both safety and immunogenicity findings from studies conducted in persons without HIV cannot be assumed to be replicated in people with HIV. Reduced immunogenicity has been observed in virologically suppressed and unsuppressed persons including those with in utero HIV exposure³⁴. Therefore, it is imperative

to include people with HIV in upcoming vaccine trials to determine potential differences in safety and immunogenicity. Models clearly show the importance of vaccines to reduce TB incidence, but these models require refinement as they have not included all the relevant parameters specific to people with HIV or those exposed³⁵. Delaying inclusion of people with HIV in TB vaccine trials results in unnecessary morbidity and mortality.

Consensus statements: There is a higher burden of TB among people with HIV and infants exposed to HIV than the general population. There are also potentially different risk-benefit profiles that must be carefully studied to generate relevant evidence for vaccine strategies among people with HIV across the TB disease and HIV spectrum. The potential individual and population level impact of novel TB vaccines targeting people with HIV should be further modelled. Mathematical modelling should also be used to develop a target product profile for TB vaccines for people with HIV and particular sub-populations (e.g., by CD4 T-cell count, age group, and TPT and ART history), and to estimate cost effectiveness and budget impact.

2. What is the landscape of TB vaccines for people with HIV?

Context: A variety of TB vaccines are being tested in early and late phase clinical trials. However, landscape assessments to date have not focused specifically on people with HIV. Certain vaccine candidates, such as live or vectored vaccines, need special assessment of safety profiles in people with HIV. Including people with HIV beginning early in clinical development avoids unnecessary delays for this population accessing vaccine products. All vaccine approaches, including POI, POD, POR, and therapeutic vaccines, should include people with HIV given their higher TB incidence, higher recurrence, and poorer treatment outcomes. People with HIV can be categorized by age group into adults/adolescents and infants/children and the strategies for TB vaccines may differ for each population. For example, pre-exposure/POI vaccines could target newborns/infants/children while pre- and post-exposure/POD strategies may be more appropriate for adolescent/adults. According to the WHO preferred product characteristics, a TB vaccine for adolescents/adults should show $\geq 50\%$ efficacy in preventing confirmed pulmonary TB, protect participants with or without past Mtb infection, and be protective in many geographical regions³⁶. For infants/children, the efficacy of a pre-exposure TB vaccine should be 80% or higher compared to baseline incidence or superior to BCG with equal or improved safety. Additionally, reduction of injection site swelling, pain, drainage, scarring and local lymphadenopathy would be improvements over BCG. As described earlier, Fig. 2 highlights the current TB vaccine pipeline and shows which vaccine candidates are being evaluated in people with HIV.

Consensus statement: Trials of TB vaccine candidates should include people with HIV with careful assessment of safety, immunogenicity and efficacy specific to people with HIV.

3. Which vaccine candidates should be prioritized for study in people with HIV on ART?

Context: As only a fraction of Mtb infected persons goes on to develop clinical disease, there are two critical time points for prevention using vaccines: pre-infection or post-infection. Pre-infection (POI) vaccine strategies are appropriate for use in newborns in endemic settings or slightly older adolescents in lower burden regions. Post-infection vaccine strategies include POD in Mtb infected persons, therapeutic vaccination in those with TB disease to reduce the proportion of TB patients with unfavourable treatment outcomes, and POR in TB patients

who have been successfully treated³⁷. TB vaccine candidates evaluated in people with HIV are summarized in **Supplemental Table 1**. Viral vectored, subunit adjuvanted and whole cell (killed) TB vaccines induce variable humoral and cellular immunity in people with HIV, although responses in ART naïve persons tend to be poorer.

Consensus statement: For adults and adolescents with HIV, subunit and non-replicating viral vectored vaccines should be prioritized, although inactivated mycobacterial vaccines may also be evaluated in this population. Novel vaccine platforms such as mRNA and DNA should be prioritized for evaluation among people with HIV, including infants and children. We encourage the evaluation of immunogenicity and safety of novel live attenuated vaccines early in development, considering possible risks and benefits for each candidate vaccine (in each age group) in people with HIV on ART. For infants and children with HIV, subunit and viral vectored vaccines should be developed, and inactivated TB vaccines may also be evaluated in this population. As live attenuated vaccines are being developed for infants, it will be important to know the safety, immunogenicity, and efficacy of these vaccines in infants with HIV on ART.

4. What are the trial design considerations of TB vaccine trials that include people with HIV?

Including people with HIV in TB vaccine trials raises many important design issues that should be considered. These trial design considerations can be divided into 8 sub-considerations: 1) participant characteristics; 2) standard of care (SOC); 3) eligibility criteria; 4) efficacy endpoints; 5) statistics; 6) ethics; 7) regulatory policies; and 8) community involvement. We have provided context and consensus statements for each sub-consideration below.

4.1: When should people with HIV be included in TB vaccine trials?

Context: People with HIV are at high risk of TB disease and would benefit from participating in TB vaccine trials as soon as safely possible to minimize the time to accessing effective TB vaccines that come to market.

Consensus statement: Among adults, adolescents, children, and infants with HIV:

Subunit, viral vectored, inactivated, and novel mRNA or DNA TB vaccines, once developed, may be evaluated in Phase 1b trials, depending on the preclinical safety profile of the candidate vaccine, and then in Phase 2, Phase 3 and post-licensure trials.

BCG and new live attenuated vaccines may be evaluated in Phase 2, Phase 3, and post-licensure trials, depending on CD4 count and viral load and if there is prospect for more benefit than harm. That is, the safety and efficacy signal in HIV-negative persons supports further development.

Pregnant women with HIV on ART:

- May be included in Phase 2, Phase 3, and post-licensure trials of subunit, viral vectored, and inactivated vaccines.
- Should not be considered for planned trials of BCG and new live attenuated vaccines, as WHO does not recommend BCG for pregnant women.

4.2: What should the SOC be for people with HIV in TB vaccine trials?

Context: An effective TB vaccine for people with HIV would complement existing tools for TB prevention in people with HIV, which includes early disease detection, prompt diagnosis and treatment, infection prevention and control, and TPT.

TPT is the WHO standard of prevention for people with HIV¹. Isoniazid preventive treatment in conjunction with ART is more effective in reducing the risk of TB than ART alone³⁸. An extended duration of isoniazid TPT was found to be equally effective as short-term rifamycin and isoniazid-based therapy in reducing TB risk in people with HIV³⁹. As the combined effect of TPT with immune modulation is greater than either intervention alone, it is reasonable to assume that TPT with TB vaccines may have a synergistic effect on reducing the risk of developing TB disease. However, offering TPT to eligible participants with HIV in TB vaccine trials may reduce the apparent effectiveness of TB vaccines. This confounder is not unlike offering pre-exposure prophylaxis (PrEP) to participants in HIV vaccine clinical trials; ethically, it is the right thing to do but does reduce the power to observe potential vaccine efficacy. Thus, next generation HIV vaccine (or other preventative strategies such as monoclonal antibodies) trials are being designed to allow for a lower incidence due to PrEP uptake⁴⁰.

Consensus statement: All people with HIV participating in TB vaccine trials must be on ART. As WHO recommends TPT as SOC for people with HIV regardless of Mtb infection status, TB vaccine trial participants with HIV (on ART), regardless of age, Mtb infection status, phase of trial (1–3) or mechanism of action (POI, POD, POR), should either previously have completed a course of TPT prior to enrolment or be offered TPT during the study if they previously have not completed a course of TPT and have no evidence of active TB disease. In trials of live attenuated TB vaccines, TPT should not be provided in the trial, as TPT may reduce the activity of live attenuated TB vaccines. Persons eligible for TPT who have not previously taken TPT should be advised to complete a course of TPT prior to enrolling in the trial.

4.3: What are the HIV-specific eligibility criteria?

Context: As CD4 + T-cell count and viral load are predictive of developing opportunistic infections, survival, and vaccine responses, these clinical characteristics should be included as eligibility criteria in TB vaccine trials that include participants with HIV. People with HIV receiving ART should therefore only be considered for inclusion in TB vaccine trials if viremia and CD4 + T-cell counts meet pre-specified thresholds.

Consensus statement: Eligibility criteria for people with HIV on ART differ depending on CD4 + T-cell count. Participants with HIV with CD4 + T-cell counts < 100 cells/mm³ or HIV RNA > 200 copies/mL:

- Should be excluded from trials of BCG and live attenuated vaccines.
- May be included in Phase 1b/2 trials of subunit, viral vectored and inactivated TB vaccines.
- May be included in Phase 3 trials if vaccines are shown to be safe and immunogenic in Phase 2 trials.

Participants with HIV with CD4 + T-cell counts \geq 100 cells/mm³ or HIV RNA < 200 copies/mL may be included in:

- Phase 1b/2 trials of subunit, viral vectored, and inactivated TB vaccines
- Phase 2 trials of live attenuated TB vaccines
- Phase 3 trials of subunit, viral vectored, inactivated, and live attenuated TB vaccines, if shown to be safe and immunogenic in Phase 2 trials.

4.4: What are the HIV-specific efficacy endpoints for people with HIV?

Context: TB among people with HIV is often paucibacillary, extrapulmonary or subclinical, particularly among those with marked immunosuppression^{41,42}. POI vaccine trials in infants, uninfected adolescents or adults evaluate Mtb infection as the endpoint. The gold standard diagnostic for Mtb infection is the interferon gamma release assay (IGRA), which measures cytokine production from Mtb antigen stimulated blood cells. Also, it has been shown that higher IGRA levels or sustained conversion predicts a greater risk of TB disease progression. Whether this holds true for people with HIV is currently unknown, as is how accurate IGRA is in this population. POD vaccine trials typically evaluate clinical, bacteriologically confirmed, pulmonary TB disease as a highly specific endpoint using solid and liquid culture methods and nucleic acid amplification assays.

Subclinical TB occurs frequently in people with HIV and may have a role in Mtb transmission. A benefit of including subclinical TB as an endpoint in POD/POR/therapeutic vaccine studies is that it may decrease the sample size and reduce the duration of follow-up, as subclinical TB would contribute to the number of endpoints and occurs earlier than clinical TB disease. The decrease in sample size, however, assumes that the vaccine will be equally efficacious at preventing clinical and subclinical TB. It's unclear whether prevention of subclinical TB should be a priority for POD, POR and therapeutic TB vaccines, for the following reasons: preventing subclinical TB would be a higher bar for the vaccine to achieve; the evidence that subclinical TB substantially contributes to TB transmission is still circumstantial; identifying and treating subclinical TB disease may compromise the ability to show efficacy against clinical TB.

Both POR and therapeutic TB vaccine trials evaluate clinical, bacteriologically confirmed, recurrent pulmonary TB disease as a highly specific endpoint using solid or liquid sputum culture; therapeutic trials additionally consider treatment failure and TB-related deaths as unfavourable outcomes in a trial. Isolates of Mtb should undergo whole genome sequencing to characterize recurrent TB as relapse or reinfection TB.

Consensus statement: Efficacy endpoints for HIV-infected participants overall should be the same as for HIV-uninfected participants in POI, POD, POR and therapeutic TB vaccine trials. As paucibacillary, extrapulmonary or subclinical TB occurs more commonly in people with HIV, consideration should be given to also include these as endpoints in TB vaccine trials among people with HIV. So as not to compromise evaluation of efficacy in preventing clinical (symptomatic) TB disease, subclinical TB should ideally only be assessed at the end of follow-up. As sustained Mtb infection is used as an endpoint in POI trials, the risk of TB among people with HIV with sustained TB infection should be established.

4.5: What are the trial design and statistical considerations?

Context: Statistical considerations for TB vaccine trials involving people with HIV include comparator arms, immune-bridging, and sample size. TPT history, participant preferences and values, and local policy should also be considered when designing POD TB vaccine efficacy trials.

Consensus statements: As a comparator arm, placebo gives the best chance of minimizing bias and is the preferred choice, except in infants for whom BCG is licensed and has shown efficacy. Therefore, a placebo should not be used in BCG-naïve infants who are well controlled on ART; rather, BCG should serve as the SOC comparator. Similarly, the comparator arms for testing safety and efficacy of live attenuated vaccines in older

children, adolescents and adults who are well controlled on ART should include BCG revaccination, in addition to placebo, to enable comparison with BCG if a new vaccine is shown to be efficacious in this age group.

We recommend using immune-bridging studies, which measure participant immune responses to vaccines rather than waiting for efficacy endpoints, for people with HIV if a correlate of protection (CoP) has been identified and people with HIV are not a sufficiently large subgroup in Phase 3 trials to permit precise estimation of efficacy.

4.6: What are the ethical considerations?

Context: People with HIV have a more urgent need for TB vaccines than the general population given their significantly higher risks of developing TB disease, drug-drug interactions¹, and poorer TB treatment outcomes¹⁻³. Consequently, delays in developing an effective TB vaccine for people with HIV would have greater individual-level consequences than for the general population. Excluding people with HIV from TB vaccine trials would worsen existing health disparities. The differentially higher burden of TB among people with HIV justifies inclusion of people with HIV in TB vaccine trials with some degree of greater in-trial risk compared to participants from the lower urgency general population.

Consensus statement: An equity-oriented research agenda that seeks to reduce disparities between people with HIV and the general population should be adopted. The timing of when to include people with HIV in TB vaccine trials should be based on consideration of risks (safety) versus the need to reduce the “time-to-evidence” for people with HIV.

4.7: What are the regulatory considerations?

Context: In order to increase enrolment of underrepresented populations, including people with HIV, in later phase clinical trials, sponsors can follow the U.S. FDA Guidance for Industry⁴³. Sponsors developing a TB vaccine are encouraged to submit an Investigational New Drug Application even if the U.S. market for that vaccine is limited and the primary target population is outside of the U.S.^{44,45}. Expedited program designations are available to facilitate development of qualifying TB vaccines for people with HIV⁴⁶. TB is on the list of qualifying tropical diseases eligible for a Tropical Disease Priority Review Voucher, which includes TB vaccines developed for people with HIV⁴⁷.

Consensus statement: Communication with regulatory authorities should occur early and throughout the development process.

4.8: How should community be involved?

Context: In the past few years, HIV vaccine efficacy trial design has been modified to account for volunteer willingness to take PrEP^{40,48}. This newer trial design was implemented after extensive community engagement and deliberations with community advisory boards (CABs) and other local leaders⁴⁹. This type of creative next-generation trial design can be applied to the TB vaccine field to ensure people with HIV are included safely. Additionally, CABs and other community stakeholders significantly enhance enrolment and retention of participants in clinical trials, especially in underserved populations^{50,51}.

Consensus statement: Community stakeholders of people with HIV should be engaged early in the process to ensure best outcomes and to provide input into study design, trial conduct, and results dissemination.

5. What is the role of immunological correlates of protection in people with HIV?

Context: Currently, there are no agreed CoPs for TB vaccines. Concerted efforts are being made to analyse immune responses from TB vaccine clinical trials that have shown some measure of efficacy^{52,53}. Identification of CoPs will enable immune-bridging studies to be performed.

Validating a CoP (in people with HIV) can be relevant for vaccine licensure and indication. A more detailed immunological characterization of people with HIV at baseline may be required, as the quality and quantity of innate and adaptive immune responses of virally suppressed individuals may vary^{54–56}.

Consensus statement: A CoP identified in people without HIV should be applied to people with HIV in immune-bridging studies. Collection of standardized sets of samples across trials is essential to enable such immune-bridging studies. Given the proportion of people with HIV that are not virally suppressed and the potential benefit from TB vaccines, inclusion of limited numbers of people with HIV who are not virally suppressed into immune-bridging studies should be considered. Immunogenicity trials (Phase 1b/2) should include people with HIV to maximize the chance of identifying a CoP that could enable immune-bridging people with HIV.

6. What are the gaps in preclinical models for studying TB vaccines in people with HIV?

Context: The nonhuman primate (NHP) model of simian and simian/HIV immunodeficiency virus (SIV/SHIV) infection recapitulates many aspects of HIV acquisition and pathogenesis. As such, it remains a valuable research tool to aid in assessing the immunogenicity and efficacy of candidate TB vaccines to model what happens in people with HIV⁵⁷.

These SIV/SHIV NHP models can help tailor preclinical studies to be relevant to people with HIV. Importantly, SIV/SHIV NHP models provide an opportunity to look at possible effects of ART and TPT co-administration; investigate impact of gut inflammation, and to study correlates in an unbiased fashion; and further understand the impact of HIV acquisition on memory immune responses from infant BCG vaccination. This platform would also be ideal for testing new vaccine regimens before doing Phase 1 studies with participants with HIV, although NHP models have not yet been shown to be predictive of protection from TB in humans. The NHP model can also help identify tissue-specific correlates that can then be measured in human trials and subsequently modify the tissue-specific assays to those that can use plasma or sputum samples. The NIH recently funded several centres to focus on preclinical models for identifying vaccine CoP⁵⁸.

Consensus statement: It is necessary to invest in NHP SIV/SHIV models (with and without ART) for TB vaccine studies. Novel vaccine platforms, such as mRNA and DNA TB vaccines, should be evaluated in NHP SIV/SHIV models, keeping in mind that NHP models have not yet been validated as predictive of protection from TB in humans.

Conclusions

We have developed a TB vaccine roadmap to accelerate the development of TB vaccines for people with HIV. The roadmap answers a number of strategic questions that make the case for including people with HIV as early as possible in clinical development and also addresses gaps in preclinical models that may portend challenges in future development of a variety of vaccine candidates. The safety and efficacy of TB vaccines in people with HIV needs to be optimized to maximize individual benefit and population level impact.

Declarations

CONTRIBUTORS

AG, JGK, and GC organised the meeting. All authors have participated in the preparation of the manuscript with contributions to draft statements in preparation for consensus, contributing to final consensus statements as panel members, drafting the manuscript, or providing revisions to content.

ACKNOWLEDGEMENTS

The U.S. National Institutes of Health (NIH), National Institute of Allergy and Infectious Diseases (NIAID), Division of AIDS (DAIDS), Cross-Network TB Vaccine Working Group report on “Developing TB Vaccines for People Living with HIV: A Roadmap” was led and written by Gavin Churchyard (ACTG), James Kublin (HVTN), Amita Gupta (IMPAACT) and Maurine Miner (HVTN), with support from Austin Van Grack (Social & Scientific Systems) under the overall direction of Judith Currier and Joseph Eron (ACTG), Glenda Gray (HVTN), Sharon Nachman (IMPAACT) and Peter Kim and Sarah Read (NIAID DAIDS). The ACTG, HVTN and IMPAACT provided support for developing the Roadmap.

The contribution of the following people who participated in various sessions is gratefully acknowledged: Austin Van Grack (DLH Corporation), Abdou Fofana (Boston University), Adrienne Shapiro (University of Washington), Alison Augustine (NIAID Division of Allergy, Immunology, and Transplantation), Ana Weinberg (EDCTP), Anchalee Avihingsanon (Thai Red Cross AIDS Research Centre), Ann Ginsberg (Gates Foundation), Catherine Yen (NIAID DAIDS), Chandler Church (University of Washington), César Boggiano (NIAID DAIDS), Chetan Seshadri (University of Washington), Corey Casper (IDRI), Dale Hu (NIAID DAIDS), Debra Benator (Washington DC Veterans Affairs Medical Center), Deepak Kaushal (Texas BioMedical Research Institute), Dereck Tait (IAVI), Richard Chaisson (Johns Hopkins University), Emily Douglass (Rutgers University), Fadzi Kasambira (NIAID DAIDS), Georgia Tomaras (Duke University Medical Center), Gerald Voss (TuBerculosis Vaccine Initiative), Hans Spiegel (NIAID DAIDS), Julia Hutter (NIAID DAIDS), Justin Shenje (South African Tuberculosis Vaccine Initiative), Katrin Eichelberg (NIAID Division of Microbiology and Infectious Diseases), Yasmin Mejia-Guevara (DLH Corporation), Lakshmi Ramachandra (NIH), Lesley de Armas (University of Miami), Linda-Gail Bekker (University of Cape Town CTU), Mamodikoe Makhene (NIAID), Mark Harrington (Treatment Action Group), Meg Trahey (Fred Hutchinson Cancer Research Center), Melanie Dubois (Boston Children's Hospital), Michael Saag (University of Alabama at Birmingham), Mike Dunne (Gates MRI), Moises Huaman (University of Cincinnati), One Dintwe (Fred Hutchinson Cancer Research Center), Patrick Jean-Philippe (NIAID DAIDS), Patty Walker (Social & Scientific Systems), Payam Nahid (University of California at San Francisco), Que Dang (NIAID), Rada Savic (UCSF School of Pharmacy and Medicine), Rebecca Reindel (US FDA), Richard Hafner (NIAID DAIDS), Savita Pahwa (University of Miami), Sai Majji (NIH NICHD), Simon Mallal (Vanderbilt Therapeutics), Stephen Carpenter

SEARCH STRATEGY AND SELECTION CRITERIA

References for this Review were identified through searches of PubMed with the search terms “TB/tuberculosis/Mycobacterium tuberculosis,” “vaccine,” “people with HIV/PWH/PLWH,” “HIV,” and “clinical trial” up until November 1, 2021. We also identified ongoing TB vaccine clinical trials involving people with HIV by searching clinicaltrials.gov, WHO International Clinical Trials Registry, and Clinical Trials Registry of India. Studies related to TB vaccine clinical trials among the general public and people with HIV were included if they were peer-reviewed and written in English. The final reference list was generated on the basis of relevance to this Review.
