## Abstract

**Background:** The prediction of potential drug-protein target interactions (DTIs) not only provides a better comprehension of biological processes but also is critical for identifying new drugs. However, due to the disadvantages of costly and high time-consuming traditional experiments, only a small section of interactions between drugs and targets in the database is verified experimentally.

Therefore, it is meaningful and important to develop new computational methods with good performance for predicting DTIs. At present, many existing computational methods only utilize a single type of molecule without paying attention to the interactions and influences between other types of molecules.

**Methods:** In this work, we developed a novel network embedding-based heterogeneous information integration model to predict potential DTIs. Firstly, a heterogeneous information network is built by combining the known associations among protein, drug, lncRNA, disease, and miRNA. Secondly, the Large-scale Information Network Embedding (LINE) model is used to learn behavior information of nodes in the network. Hence, the known drug-protein interaction pairs can be represented as a combination of attribute information (e.g. protein sequences information and drug molecular fingerprints) and behavior information of themselves. Thirdly, the Random Forest classifier is used for training and predicting.

**Results:** In the results, under the 5-fold cross validation, our method obtained 85.83% prediction accuracy with 80.47% sensitivity at the AUC of 92.33%. Moreover, in the case studies of three common drugs, the top 10 candidate targets have 8 (Caffeine), 7 (Clozapine) and 6 (Pioglitazone) are respectively verified to be associated with corresponding drugs.

**Conclusions:** In short, these results indicate that our method can be a powerful tool for predicting drug-protein interactions and finding unknown targets for certain drugs or unknown drugs for certain targets.
