Abstract

Deep soft soil of the Yangtze River floodplain in Nanjing has a special interlayer structure, which provides favorable conditions for the application of vacuum tube-well dewatering technology. This paper focuses on the design, construction and treatment effect of vacuum tube-well dewatering technology. The hydrological parameters and the hydraulic connections between the various layers of the site have been ascertained through two simple single-well multi-holes pumping tests. Moreover, the layout of vacuum tube-wells and depressurization wells in a test site with 84m length and 84m width was designed based on the above parameters. Field tests of vacuum tube-well dewatering technology were conducted on the test site. And the changes of groundwater level, ground settlement and pore water pressure during the test was monitored. The CPTU test technology was used to quickly evaluate the engineering properties of the site before and after treatment. Finally, combined with the settlement monitoring data, the hyperbolic method was used to predict the final settlement. The results indicated that consolidation efficiency of vacuum tube-well dewatering technology has obvious advantages. Implications of this study can provide a reference for the construction design of the site's ground improvement consolidation and other similar projects.

Keywords: vacuum tube-well · pumping test · ground settlement · water drawdown level · CPTU · Yangtze River Floodplain

1 Introduction

In the downstream reaches of the Yangtze River, the sedimentary particles range from coarse to fine owing to the separation of water flow, making the soft soil in this region have the characteristics of silt clay mixed with fine sand (Iqbal et al. 2005; Cai et al. 2017). In addition to high water content, high compressibility, low shear strength, and low permeability coefficient, this kind of soil is often buried deep, and the underlying sand layer is hydraulically connected to the Yangtze River (Xia et al. 2006; Shi et al. 2016). The engineering geological conditions are extremely complicated. With the advancement of the Yangtze River Economic Belt strategy in China, engineering construction is increasing on the floodplain of the Yangtze River. The foundation treatment project of this kind of soil has become a research hotspot of engineers.

At present, vacuum preloading method is one of the most popular methods for soft clay and dredger fill in coastal and riverside areas (Ding et al. 2019; Griffin and O'Kelly 2014). However, vacuum

42 preloading method takes a long time to process, and vacuum degree will attenuate along with depth,
43 which causes its effective depth to be limited (Indraratna 2010; Chai 2005; Shen et al. 2013). Besides,
44 vacuum preloading method will cause fine-grained soil to move around the PVD board and cause
45 blockage, making its performance worse than expected (Wang et al. 2017; Lei et al. 2017; Wang et al.
46 2016).

47 In the traditional tube-well dewatering method, the pump are set at the bottom of the wells. The water
48 is pumped up from the bottom through a pipe to a discharge point(Han 2015; Sargent et al. 1998). The
49 method is suitable for the layers with abundant underground aquifers and large soil permeability($>$
50 1.2×10^{-3} cm/s) (Cashman and Preene 2020; Zhang 2017). The application of vacuum technology in
51 tube-well can solve the problem of impermeable aquifer and interlayer stagnant water, and expand the
52 application scope of tube-well dewatering. Vacuum tube-well technology reduces the pore water
53 pressure by pumping groundwater, and increases the effective stress of the soil, thereby improving the
54 strength of the foundation (Han 2015). Vacuum tube-well technology not only retains the advantages of
55 tube-well dewatering, such as large dewatering depth and fast dewatering speed, but also can increase
56 negative pressure in any well section according to formation conditions and engineering needs to
57 absorb saturated water in cohesive soil and residual water at the interface. In principle, it is applicable
58 to the above-mentioned deep sand-clay in the Yangtze River Floodplain.

59 Many scholars have researched the treatment mechanism and influencing factors of vacuum tube-well
60 technology through theoretical analysis (Shen and Xu 2011; Indraratna et al. 2005; Wu et al. 2016),
61 field tests (Pan 2016; Ren 2011), and numerical simulation (Ahmad et al. 2019; Luo et al. 2008).
62 Rujiliatkamjorn et al. (2007) gave an analytical solution of the consolidation settlement of
63 vacuum-assisted vertical and horizontal drainage. Huang (2014) used regression analysis method, grey
64 forecasting method and neural network method to predict the settlement of vacuum tube-well field
65 experiment, and an effective stress model for steady seepage of saturated soil under vacuum conditions
66 is established. Nie et al. (2014) analyzed of the impact of a single row of well-point spacing on the
67 treatment effect and found that after shortening the pumping well spacing, the dewatering effect was
68 significantly improved. Indraratna et al. (2000) developed an equal plane strain model to perform
69 numerical simulation analysis on tube-well drainage. Vertical tube-wells significantly increased the soil
70 settlement rate, improved the dissipation of pore water pressure, and reduced the lateral deformation of
71 soft clay foundations. Jia et al. (2014) established a three-dimensional groundwater flow model to
72 divide the seepage field of groundwater around a vacuum well-point into a vacuum disturbance zone, a
73 joint influence zone of vacuum and gravity, and a gravity influence zone. Currently, vacuum tube-well
74 technology is mainly used for foundation pit dewatering, and its application in soft foundations is
75 generally used as an auxiliary dewatering method combined with other foundation treatment methods
76 (Liu et al. 2016; Liu et al. 2009). This method is still less applied in the treatment of large-area deep
77 soft foundation in the Yangtze River floodplain, and its treatment performance lacks field test
78 verification.

79 This study uses two single-well multi-holes pumping tests to prove the hydrogeological conditions and
80 hydraulic connection of the site in the Yangtze River Floodplain. Then the foundation was consolidated
81 by vacuum tube-well dewatering technology. The groundwater level, pore water pressure, ground
82 settlement, combined with CPTU in-situ testing technology, evaluated the site's bearing capacity and
83 physical and mechanical indexes before and after treatment. The research results can provide a

84 reference for the construction design of the site's ground improvement consolidation and other similar
85 projects.

86 2 Ground conditions and soil characterization

87 This site of field test is shown in Fig.1. The westernmost part of the site is about 400m away from the
88 Yangtze River. The landform of the site is alluvial floodplain on the edge of terrace, and the soft soil is
89 widely distributed. To reduce post-construction settlement, the soft soil needs to be treated to accelerate
90 its consolidation. According to the results of drilling exploration, the engineering geological section
91 map of the site is shown in Fig.2(a), and the main physical and mechanical indicators of the rock and
92 soil layers are shown in Table 1. The CPT and SPT profiles to a depth of 30 m of the test site are
93 presented in Fig.2(b) and Fig.2(c), respectively.

94 Through the analysis of soil samples of different layer, it is found that the soft soil layer of the site has
95 a special structure. The clay layer is sandwiched with a thin layer of silt sand, and obvious horizontal
96 thin bedding is formed (Fig.2(d)). In layer 2-②, this structure is particularly obvious. These silt sand
97 interlayers become channels for the horizontal movement of groundwater, which is beneficial to lower
98 the groundwater level and reduce pore water pressure. However, the tube-well dewatering belongs to
99 the category of gravity drainage, and its suction height is limited to a certain extent. It is more suitable
100 for soils with larger permeability coefficients rather than soft clay. By pumping a vacuum in the
101 tube-well to form a negative pressure, it can accelerate the movement of groundwater in the interlayer
102 to the tube-well and solve the above problems.

103 **Table 1** Basic physical and mechanical properties of soil

soil layer	type of soil layer	$w(\%)$	$\gamma(\text{kN/m}^3)$	e	I_L	I_P	$\alpha_{1-2}(\text{MPa})^{-1}$	$E_{S1-2}(\text{MPa})$	$C_k(\text{kPa})$	$\Phi_k(^{\circ})$

4-②	weathered andesite	saturated uniaxial compressive strength of rock $f_{ik}=9.91\text{MPa}$ (standard value)								

104 Note: w —moisture content; γ —unit weight; e —void ratio; I_L —liquidity index; I_P —plasticity index;

105 α_{1-2} —compressibility coefficient; E_{S1-2} —compression modulus; C_k —cohesion; Φ_k —friction angle

106 The types of groundwater in the site are mainly pore phreatic water and micro-confined water that
107 occur in the Quaternary loose layer. The phreatic aquifers include layer 2-① and layer 2-②. The layer
108 3-① is confined aquifer, which has a certain hydraulic connection with the upper phreatic water and is
109 the vertical replenishment source for the upper soft soil layer. After the confined water level is reduced,
110 the replenishment of the upper soft soil layer is effectively reduced, and the groundwater in the soft soil
111 layer can penetrate into the lower silt fine sand layer through the crisscross interlayer, which
112 accelerates the consolidation and settlement of the upper soft soil. The main sources of phreatic water
113 replenishment are atmospheric precipitation and surface runoff, and the main discharge method is
114 natural evaporation. In the horizontal direction, the confined aquifer ends at about 80m~100m outside
115 the site, and beyond the end position is the clay layer. Therefore, the clay layer can be used as a
116 horizontal impermeable boundary, while in the vertical direction, the underlying bedrock is used as
117 impermeable boundary. The buried depth of the first sight water level measured during the exploration

118 is 0.5m~3.1m below the natural ground, and the stable groundwater depth is 0.6m~3.2m below the
 119 natural ground, and the elevation is 0.96m~5.0m. The groundwater level changes seasonally and
 120 periodically. According to the hydrogeological data of the Nanjing area, the annual change of the
 121 phreatic water level is generally about 2.0m. The elevation of the confined water level is generally
 122 around 3.5m.

3 Single-well multi-holes pumping test and result analysis

3.1 Test scheme

130 In order to ascertain the permeability, water outflow and water richness of phreatic aquifer and
 131 confined aquifer at the test site, and to determine the relevant hydrogeological parameters, as well as

132 provide design references for the construction of vacuum tube-well. Two single-well with multi-hole
 133 observations tests were conducted on the confined aquifer and phreatic aquifer respectively. The
 134 pumping tests adopt reverse circulation rotary drilling to form holes. Then the tube well is put into the
 135 hole, clean the side wall of the tube well to prevent blockage. Finally, the filter material
 136 (medium-coarse sand) is fixed between the sidewall of hole and the sidewall of tube well. The specific
 137 test scheme is as follows:

138 (1) *Confined aquifer*: The main pumping well is ZJ01, the well depth is 27m, and the well diameter is
 139 273mm. Five observation holes are set simultaneously (GC01, GC02, GC03, GC04, GC05). The
 140 arrangement direction of GC01, GC02 is perpendicular to impermeable boundary, while the
 141 arrangement direction of GC03, GC04 is parallel to the impermeable boundary. The depth of
 142 observation holes is the same as that of the main well. In addition, set the GC05 hole as the phreatic
 143 level observation hole with a depth of 22m, which is used to observe the change of phreatic water level
 144 during the extraction of confined water. The specific layout is shown in Fig.3. The single well
 145 multi-hole pumping test of confined aquifer started on May 8, 2020. The pumping process lasted for 16
 146 hours. After the pumping was stopped, the water level recovery observation was carried out. The
 147 observation time was about 20 hours.

148 (2) *Phreatic aquifer*: The main pumping well is ZJ02, the depth of the well is 24m, and the well
 149 diameter is 273mm. Six monitoring holes are set simultaneously (GC06, GC07, GC08, GC09, GC10,
 150 GC11). The depth of the observation holes is consistent with the depth of the main pumping well. The
 151 specific layout is shown in Fig.3. The single well multi-hole pumping test started on May 11, 2020.
 152 The pumping test lasted for 14hours. After the pumping was stopped, the water level recovery
 153 observation was carried out. The observation time was about 6 hours.

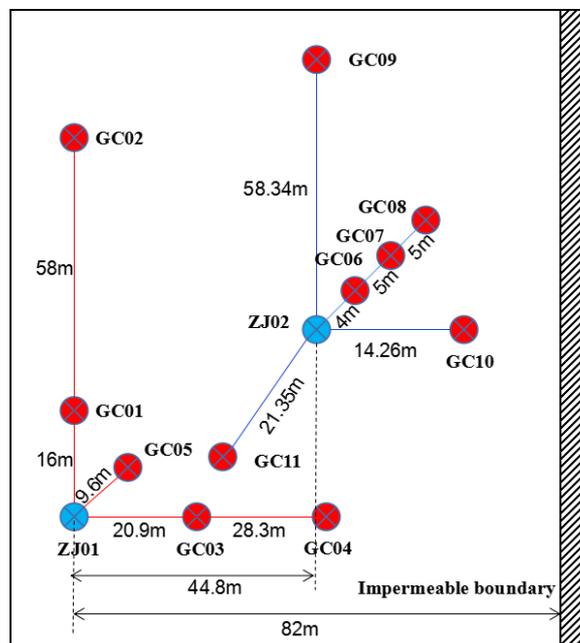

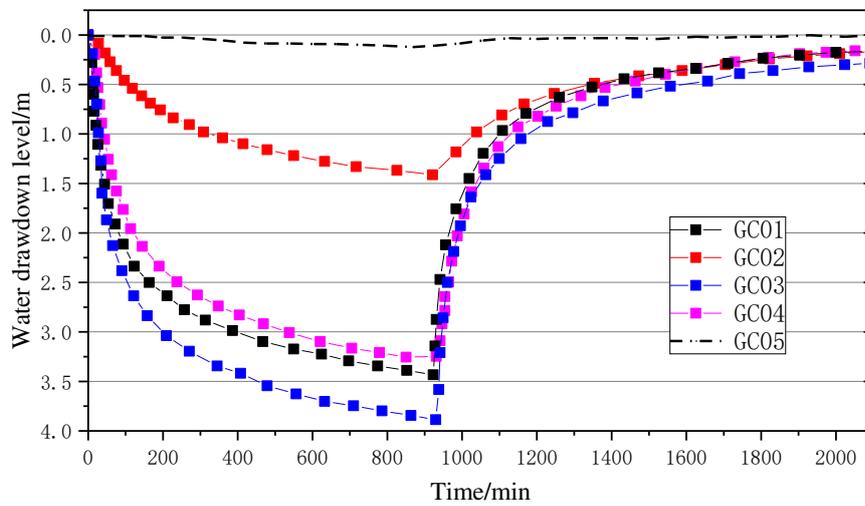

Fig.3 Layout drawing of pumping test.

154
 155

3.2 Test results of confined aquifer

156
 157 The initial water level elevation of the confined aquifer measured on site is about 3.05m~3.19m. Fig.4
 158 shows the curve of the water drawdown level of each observation hole with time. In the early stage of
 159 pumping, the water drawdown level drops quickly, and after 120 minutes, it starts to slow down. To the

160 end of pumping, the water drawdown level of each observation well is between 1.4m and 3.87m.
 161 Because hole GC02 is far away from the main well, the water drawdown level is the smallest. However,
 162 The GC01, GC03, and GC04 water drawdown levels are relatively close, and one of the GC03 water
 163 drawdown level is the most, which is 3.87m. After the pumping was stopped, the confined water level
 164 of the observation wells recovered faster. It shows that the confined aquifer has a certain supply source.
 165 In addition, the phreatic observation hole GC05, about 9.6m away from the main pumping well, was
 166 observed. During the pumping period, the water drawdown level is 5cm. After pumping was stopped,
 167 the depth of the phreatic aquifer changed from 2.98m to 2.91m, which risen by 7cm. It can be seen that
 168 although the phreatic level changes little during the pumping process, the water level changes are
 169 synchronized with the pumping process, indicating that there is a certain hydraulic connection between
 170 the phreatic aquifer and the confined aquifer, but the hydraulic connection is very weak and can be
 171 ignored in construction.

172
 173 **Fig. 4** Curve of water drawdown level of each observation well with time (confined aquifer)

174 Combined with the water drawdown level data of each observation hole and the monitoring of outflow.
 175 According to the hydrogeology manual of China (China Geological Survey Bureau, 2013), using the
 176 Eq.(1)~Eq.(4) for the complete well in the confined aquifer, the permeability coefficient,
 177 transmissibility coefficient and influence radius of the confined aquifer can be obtained. The
 178 calculation diagram is shown in Fig.5, and the calculation results are shown in Table 2. After
 179 calculation, the permeability coefficient of the confined aquifer is $K \approx 9.38 \sim 13.55$ m/d, the average
 180 permeability coefficient $K = 11.46$ m/d, the average transmissibility coefficient is 50.42 m²/d, and the
 181 average influence radius is 345m.

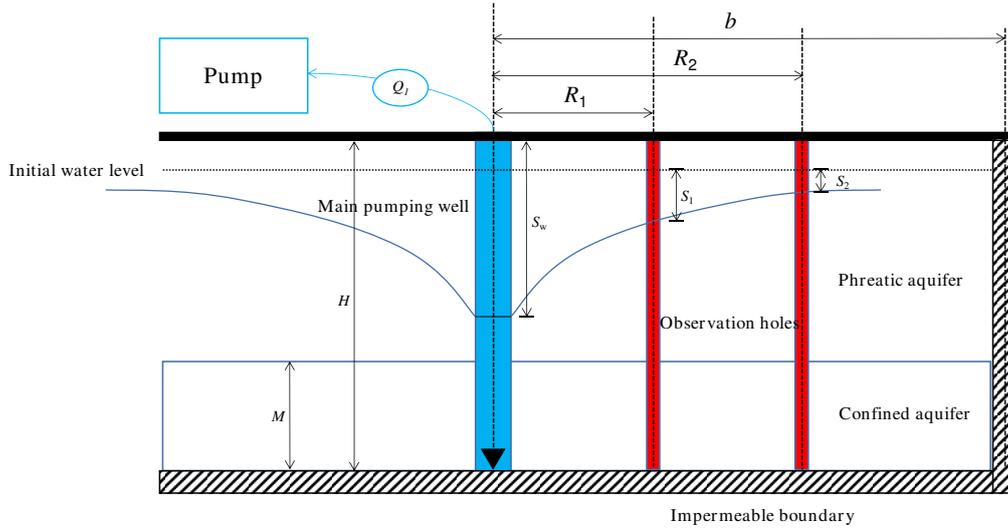

Fig. 5. Simplified diagram of calculation for water pumping test of confined aquifer

When the observation holes are perpendicular to impermeable boundary,

$$K = \frac{0.366Q_1}{M(S_1 - S_2)} \lg \frac{R_2(2b - R_2)}{R_1(2b - R_1)} \quad (1)$$

When the observation holes are parallel to impermeable boundary,

$$K = \frac{0.366Q_1}{M(S_1 - S_2)} \lg \frac{R_2 \sqrt{(4b^2 - R_2^2)}}{R_1 \sqrt{(4b^2 - R_1^2)}} \quad (2)$$

$$R = 10S_w \sqrt{K} \quad (3)$$

$$T = KM \quad (4)$$

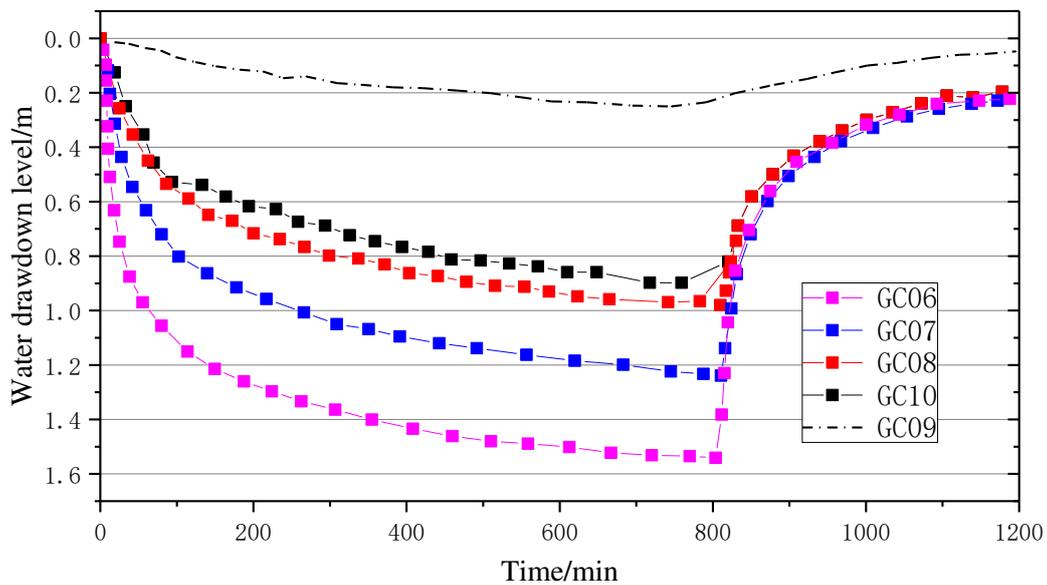

Where, M is the thickness of the confined aquifer(m); S_1 , S_2 are the water drawdown level of the two observation holes(m); R_1 , R_2 are the center distance between the two observation holes and the pumping well(m); Q_1 is water outflow of the pumping well(m^3/d); K is permeability coefficient(m/d); b is the distance of the pumping well from the impermeable boundary(m); R is influence radius(m); T is transmissibility coefficient(m^2/d); S_w is water drawdown level of the main pumping well(m).

Table 2 Test results of confined aquifer

direction	number	R_1/R_2 (m)	S_1/S_2 (m)	Q_1 (m^3/d)	b (m)	M (m)	K (m/d)	R (m)	T (m^2/d)
paraller	GC01	16	3.40	365	82	4.4	9.38	378.41	59.60
	GC02	74	1.40						
perpendicular	GC03	20.9	3.86	365	82	4.4	13.55	312.36	41.26
	GC04	49.3	3.24						

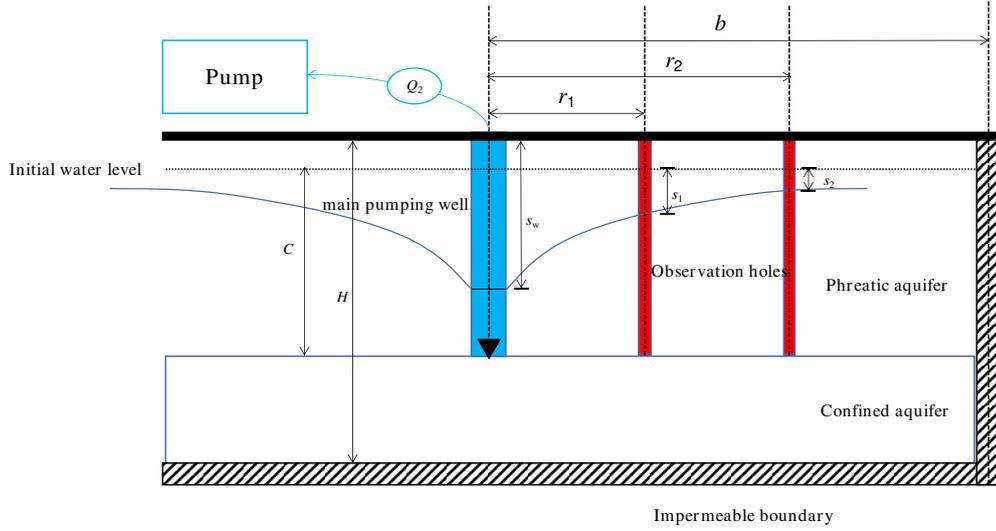

201 **3.3 Test results of phreatic aquifer**

202 The initial water level of the phreatic aquifer measured on site is about 5.66m~5.837m. Fig.6 shows the
 203 curve of the water drawdown level of each observation hole with time. The variation trend of this curve
 204 is similar to the confined aquifer. However, from the depth of water drawdown, each observation hole
 205 in the phreatic aquifer is lower than that of the confined aquifer. After pumping, the water drawdown
 206 level in each observation hole is between 0.21m and 1.56m. One of the observations well GC06, which
 207 is closer to the main well (4.31m), it has the largest water drawdown level of 1.56m. It indicates that
 208 the water permeability of the phreatic aquifer is less than the confined aquifer. In addition, the
 209 observation hole GC08, which is far away from the main well (58.34m), has a water drawdown level of
 210 0.21m, and still retains a certain downward trend, reflecting that the phreatic aquifer has a certain
 211 permeability and range of influence.

212 **Fig.6** Curve of water drawdown level of each observation well with time (phreatic aquifer)

213 Similarly, using Eq.(5) and Eq.(6) for complete wells in phreatic aquifers, the permeability coefficient
 214 and influence radius are calculated. The calculation diagram is shown in Fig.7, and the calculation
 215 results are shown in Table 3. From the results, the permeability coefficient of the phreatic aquifer is
 216 $K=0.76\text{m/d}\sim 1.05\text{ m/d}$, the average permeability is $K=0.86\text{ m/d}$, and the influence radius is about
 217 $81\sim 244\text{m}$. Due to the large difference in the calculated influence radius, the graphic method (Han 2015)
 218 is applied to find influence radius as shown in Fig.8. This method uses the curve between water
 219 drawdown level and distance to connect and extend. When the water drawdown level to zero, the
 220 corresponding distance is the influence radius. According to Fig.8, it is recommended that the influence
 221 radius of the phreatic aquifer is 130m.
 222

223

	GC09	58.34	0.21				

233
234 **Fig.8** Graphic Method

235 In summary, according to the pumping test, the hydrogeological parameters and hydraulic connections
236 of the confined water layer and the phreatic layer were obtained, which can provide design basis for the
237 layout, number, and spacing of the decompression wells and vacuum tube-wells.

238
239 **4 Field Test of Vacuum Tube-well Technology**

240 In order to analyze the feasibility of vacuum tube-well dewatering technology for improving the soft soil
241 in Yangtze River floodplain. An area with 84m long and 84m wide was selected for the field test.
242 Through monitoring groundwater level, surface subsidence, pore water pressure, combined with CPTU
243 in-situ testing technology to summarize and evaluate the treatment performance.

244 **4.1 Test scheme**

245 In the construction of tube-well dewatering, the layout of dewatering wells is of great significance to
246 the treatment effect. The number of dewatering wells can be calculated according to total outflow of
247 the site and the outflow of single dewatering well. The specific calculation method is shown in
248 Eq.(7)~Eq.(10). (Ministry of Housing and Urban-Rural Development of China 2016; Han 2015)

249
$$n = \lambda Q/q$$

250 (7)

251
252 Where, n is the number of dewatering wells; Q is the total outflow(m^3/d); q is the outflow of single
253 well(m^3/d); λ is the adjustment coefficient, taken as 1.2.

254 For phreatic well (dewatering for phreatic aquifer), The total outflow includes recharge Q_r and static
255 reserves Q_s .

256
$$Q_r = \pi K \frac{(2C - S_d) S_d}{\ln(1 + \frac{R}{r_0})}$$

257 (8)

258 $Q_s = AS_w\mu/t$

259 (9)

260

261 Where, r_0 is equivalent radius, $r_0 = \sqrt{A/\pi}$ (m); A is field area(m²); μ is yield of water, taken as 0.1
 262 according to experience; t is design dewatering time(d); S_d is design dewatering depth(m); C is the
 263 thickness of the phreatic aquifer(m).

264 For depressurization well (dewatering for confined aquifer), the total outflow can be calculated as
 265 follow,

266 $Q = 2\pi K \frac{MS_d}{\ln(1+\frac{R}{r_0})}$ (10)

267 Where, M is the thickness of the confined aquifer(m); K is permeability coefficient(m/d).

268 The field test site is an area with 84m long and 84m wide. With reference to the calculation results of
 269 the single-well multi-hole pumping test, combined with Eq. (7)~Eq. (10), the number of phreatic wells
 270 and depressurization wells in the site can be obtained. The calculation results are shown in Table.4.

272

Table 4 Design and calculation results of drainage wells

types of well	A(m ²)	C/M(m)	S _d (m)	R(m)	r ₀ (m)	t(d)	Q _r (m ³ /d)	Q _s (m ³ /d)	Q (m ³ /d)	n
phreatic well	7056	21	15	130	47.5	20	829	529	1493	33
Depressurization well	7056	4.4	15	345	47.5	20	/	/	2248	9

273 Based on the above calculation results, while considering the graphic design. The phreatic wells are
 274 arranged in a square shape with a spacing of 14m, a total of 36. In addition, a set of 7m spacing and a
 275 set of 5m spacing are arranged in the field for comparison, which can compare the influence of
 276 different well spacing on the effect of dewatering and consolidation. It is important to note that seven
 277 wells of SG01~SG05, SG08, and SG15 use no-vacuum tube-wells, and the remaining phreatic wells
 278 use vacuum tube-wells. Depressurization wells are arranged in the outer circle of the field with a
 279 spacing of 28m, a total of 12. The number of depressurization wells is slightly higher than the
 280 calculation result, mainly because the site is located around the Yangtze River and the hydraulic
 281 connection is more complicated. Therefore, several depressurization wells have been added to ensure
 282 the treatment effect. The layout of wells in the site are shown in Fig.9

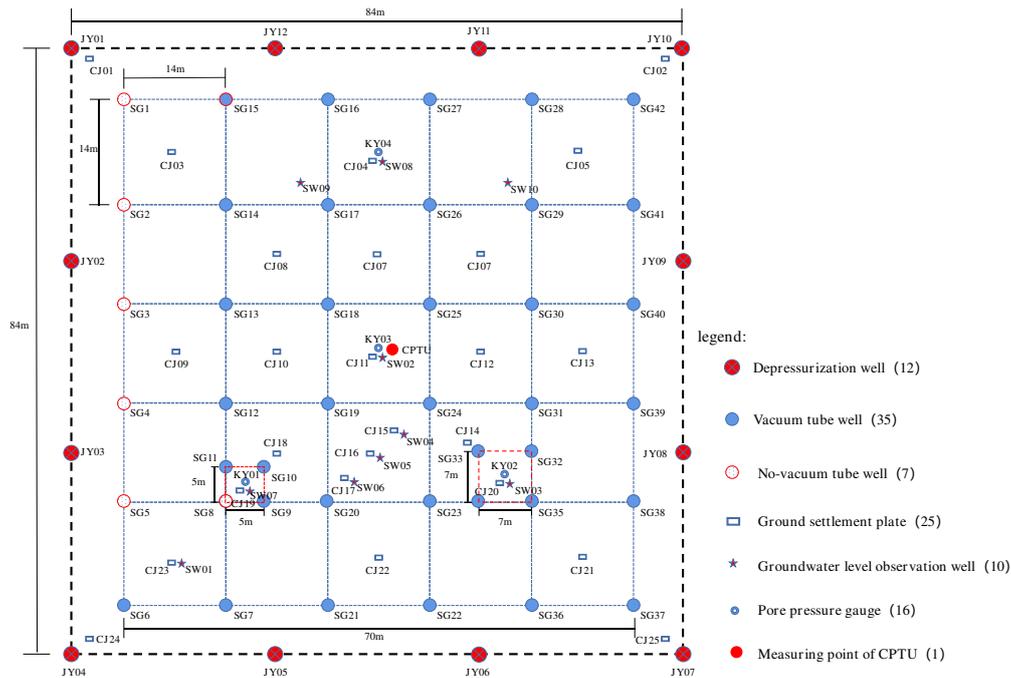

Fig. 9 The layout of the site and the location of each monitoring point

283

284

285 The construction of the vacuum tube-well is carried out according to the following steps. Firstly,
 286 reverse circulation drilling is used to form the hole with a diameter of 450mm (Fig.10(a)).
 287 Subsequently, the suspension method is used to put in the vacuum tube-well. (Fig.10(b)). The vacuum
 288 tube-well is proposed to use a steel pipe with a diameter of 273mm (outer diameter). The steel pipe has
 289 filter holes in the aquifer. And the holes are wrapped with a 60 mesh nylon filter. The depth of the
 290 vacuum tube-well is about 24m. After the vacuum tube-well is fixed, immediately backfill the filter
 291 material (Fig.10(c)). The filter material used is medium-coarse sand. Finally, use a pump to wash the
 292 well until the well water reaches the specification requirements (Fig.10(d)). The upper part 3m-4m of
 293 wells is sealed with cement slurry and a sealing cap on the top of the well to ensure the vacuum
 294 condition in the well. Four vacuum tube-wells share a vacuum pump as shown in Fig.11. In the early
 295 stage of dewatering operation, vacuum pump is applied to the dewatering well, and the vacuum degree
 296 is not less than 60kPa. Vacuum pumping is performed alternately with a vacuum pump and a
 297 submersible pump. The pumping interval of the submersible pump ranges from short to long. Each
 298 time the water in the dewatering well is drained, the pump is stopped immediately. For wells with a
 299 large amount of water, the number of pumping times per day will increase accordingly. The opening
 300 and closing of the submersible pump are controlled automatically.

301 The construction steps of depressurization wells are similar to those of the vacuum tube-wells, except
 302 that the pump of the depressurization wells is arranged in the confined aquifer, so its length is about
 303 27m. And the upper part of wells depressurization is sealed with clay slurry. The permeability
 304 coefficient of the confined aquifer is large, so vacuum pumps are not used.

305 Arranging ground settlement plates, layered settlement holes, groundwater level observation wells,
 306 pore pressure gauges at different locations on the site. And use the CPTU test vehicle to test the
 307 changes in the soil engineering properties before and after the treatment. The layout of the site and the
 308 location of each monitoring point are shown in Fig. 9.

Fig.11 Structure and connection of wells

315

(1) CPTU field test

316

Use the in-situ CPTU technology to test the soil properties before and after the reinforcement. CPTU test adopts SEU@CPTU-2 digital multi-function CPTU holes pressure static penetration probe system, equipped with multi-function digital probe. Not only can measure the cone tip resistance q_c and sidewall friction f_s , but also the pore water pressure u and the dissipation process of excess pore water pressure in the soil layers below the groundwater level can be tested (Cai et al. 2009).

320

321 (2) *Groundwater level observation well*

322 The groundwater level observation well is mainly used to observe the drop of the phreatic level (water
323 level of the soft soil layer) in the test site. Ten observation wells are arranged in different positions in
324 the site. The water level observation well has a depth of 24m, a diameter of about 450mm, and a
325 double-walled corrugated pipe with a diameter of 250mm.

326 (3) *Ground settlement plate*

327 Ground settlement plates are used to monitor changes during the processing. A total of 25 ground
328 settlement was set up and buried in the undisturbed soil, evenly distributed around and in the middle of
329 the site.

330 (4) *Pore water pressure gauges*

331 Pore water pressure gauges are used to monitor changes in pore pressure during treatment. The pore
332 water pressure gauges are buried in the center of the tube-wells with different spacing, divided into
333 three groups, and an additional group is added at the center of the site, each group has 4, a total of 16,
334 and the buried depths are 15m, 20m, 25m, and 30m.

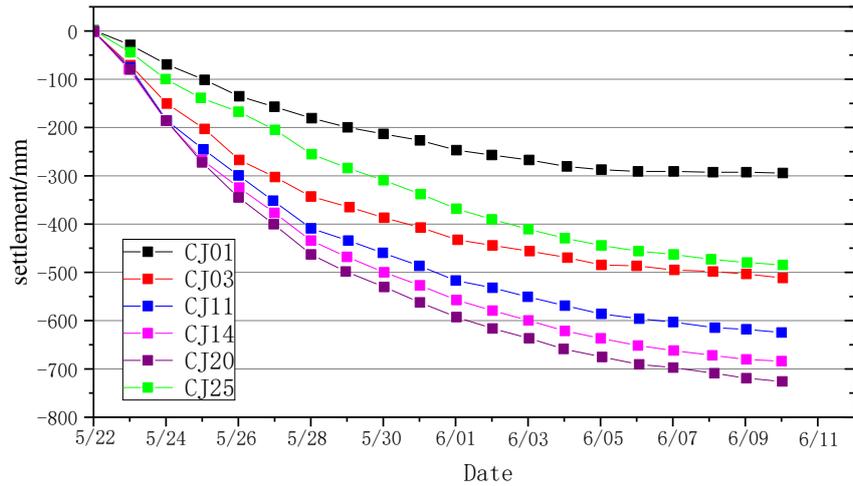

335 The monitoring instruments were buried in accordance with the test plan, the initial values were
336 collected, and the CPTU data of the in-situ soil was measured. The field test began on the morning of
337 May 23 and ended on June 11 for a total of 20 days. During the pumping process, the ground
338 settlement, groundwater level, and pore water pressure are monitored. After the pumping is completed,
339 the treated soil is tested again with CPTU.

340 **4.2 Ground settlement**

341 Fig.12 shows the variation curve of cumulative ground settlement over time for some typical
342 monitoring points. It can be seen that as the groundwater is pumped out, the surface settlement
343 gradually increases. This is mainly because the pore water pressure of the soil decreases and the
344 effective stress increases, which causes the soil to consolidate. Among the monitoring points, CJ20 has
345 the largest surface subsidence at 726mm, which is located at the center of the well spacing of 7m. CJ19,
346 which is located at the center of the 5m well spacing, and its settlement is 597mm. The settlement of
347 the site center CJ11 point is 628mm. The average ground settlement within the diving well group is
348 about 611mm.

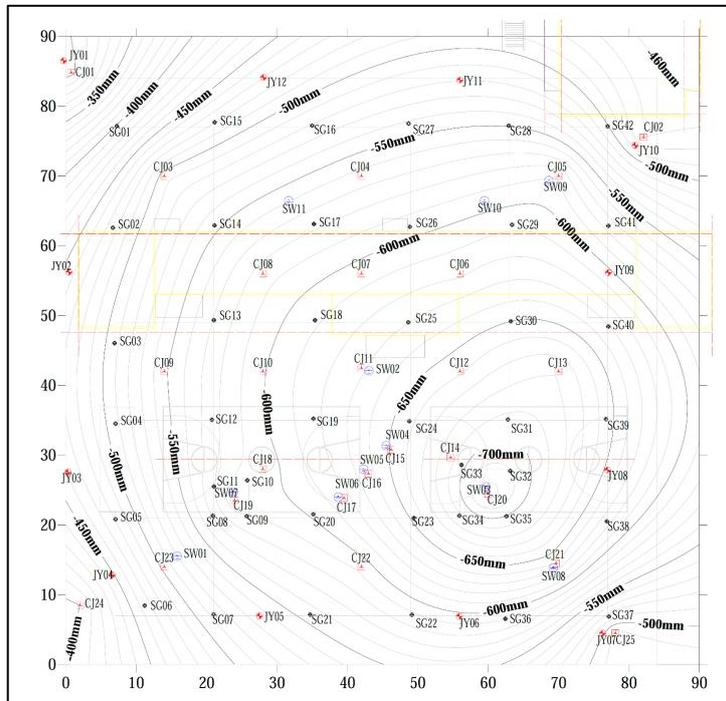

349 The contour map of the ground settlement of the test site is shown in Fig.13. The settlement of the
350 entire site decreases radially from the center to the surrounding with 7m spacing wells. It is generally
351 believed that after shortening the spacing of pumping wells, the dewatering effect will be significantly
352 improved. However, the settlement of the tube-well spacing of 7m is greater than that of 5m in this site.
353 This is mainly because each tube-well has a dewatering influence range. When the distance between
354 the tube wells is too large, the dewatering treatment range is limited; when the distance between the
355 tube-wells is too small, the mutual interference of the vacuum zones between different tube-wells
356 inhibits the dewatering effect. Therefore, there is an optimal spacing for the vacuum tube-well
357 dewatering method. On this site, the space of 7m is better.

358 Another observation is that the settlement on the left side of the test site is relatively small, which is
359 believed to be related to the lack of vacuum pumping in nearby submersible wells. Vacuum tube-well
360 dewatering can form negative pressure around the pipe inlet, accelerate pumping, reduce pore water
361 pressure in the soil, and increase pumping rate and consolidation efficiency.

362
363

Fig.12. Variation curve of cumulative ground settlement over time for some typical monitoring points

364

Fig.13. Contour map of the ground settlement

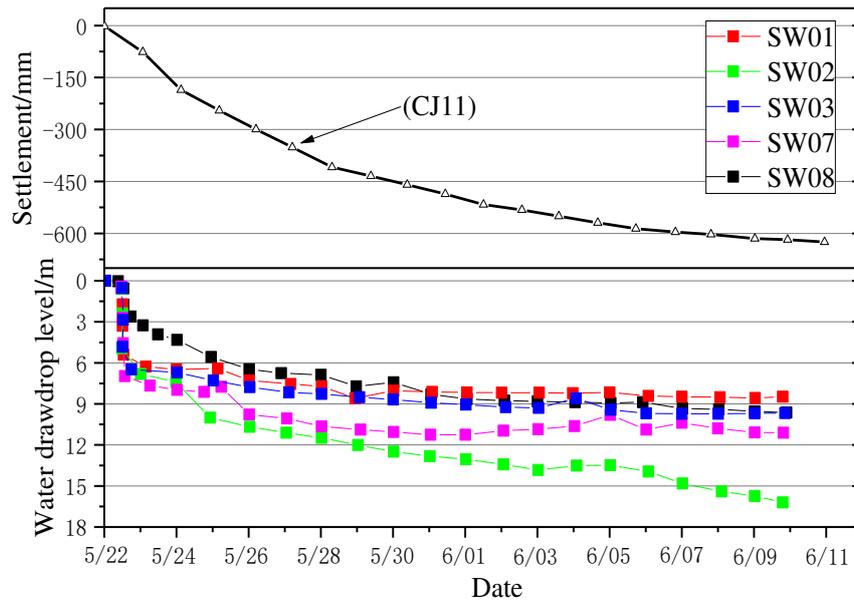

365
366

4.3 Groundwater level

368 The groundwater levels at different locations on the site were monitored. Fig.14 shows the variation
 369 curves of the groundwater levels at some typical monitoring points with pumping time. As shown in
 370 Fig.14, as the pumping continues, the depth of the groundwater level gradually decreases. The phreatic
 371 level is basically reduced to the buried depth of 10~13m, and the water drawdown levels to about
 372 9~11m. Among them, the water level of SW03 drops to a buried depth of 18.6m, and the water
 373 drawdown levels to about 16.7m. This point is located at the center of the 7m well spacing and
 374 corresponds to the point CJ20 with the largest amount of ground settlement.

375 However, it is interesting to observe that comparing the water level drawdown curve and the settlement
 376 curve, it can be found that the settlement curve is of a “slow drop type”, that is, as the groundwater is

377 pumped out, the settlement keeps increasing at a slower rate. The water level drawdown curve shows a
 378 "steep drop-slow drop type". Initial pumping, the water drawdown levels very quickly, the water level
 379 within 24 hours drawdown reduces by about 80% of the total depth value. After 24 hours, the water
 380 level continues to decrease, but the magnitude reduction slowed. This is mainly because the test site is
 381 a soft soil and deep water-rich sand layer with a large drainage distance, so the consolidation rate is
 382 slow. Pumping water in this type of formation will cause the groundwater level to change quickly and
 383 stabilize in a short time. However, due to the large drainage distance, settling speed is slower than
 384 dewatering speed.

385

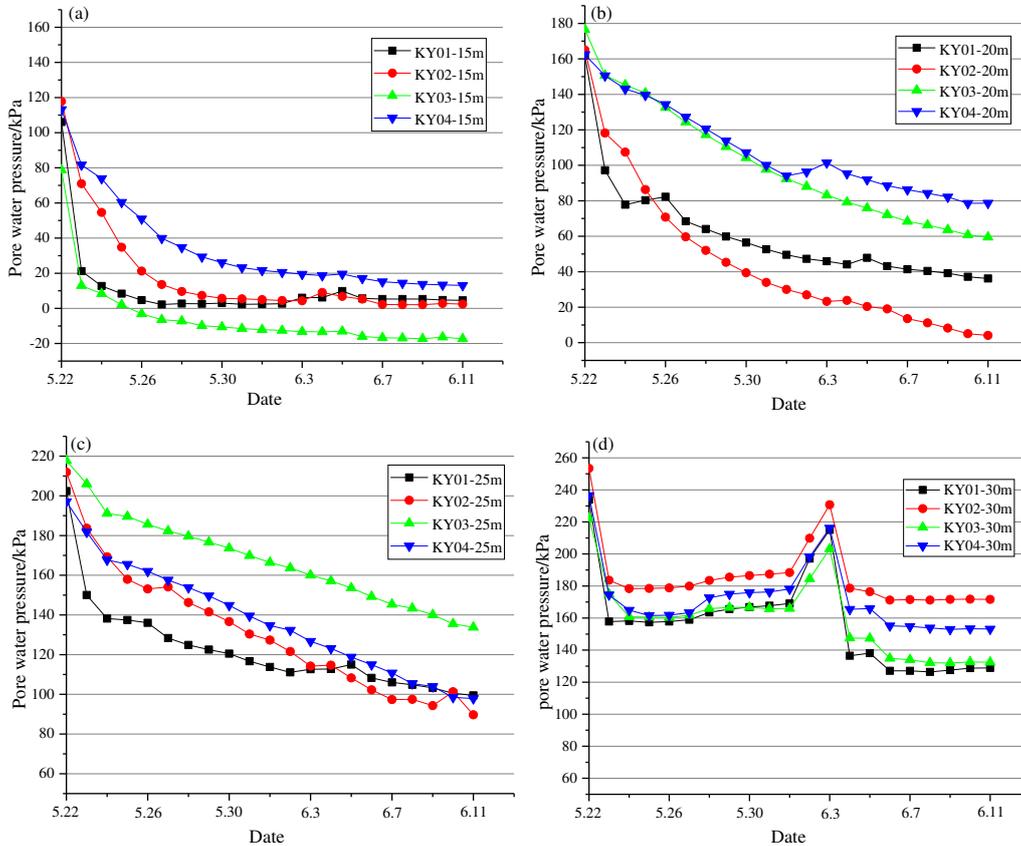

386 **Fig.14.** Variation curves of the groundwater levels at some typical monitoring points

387

388 **4.4 Pore water pressure**

389 To analyze the pore water pressure changes at different depths in the site during the pumping process, 4
 390 sets of pore water pressure gauges were buried in the center of the three well spacing and the center of
 391 the site, respectively, KY01 (5m), KY02 (7m), KY03 (site Center), KY04 (14m). The pore pressure
 392 dissipation of each group of pore pressure gauges at the same depth varies with monitoring time as
 393 shown in Figure 13. It can be seen that the pore pressure dissipation curve is similar to the water
 394 drawdown level curve. The pore pressure dissipates faster in the early stage and slows down in the later
 395 stage. The pore water pressure dissipation value caused by pumping is about 90kPa~120kPa, which
 396 corresponds well to the groundwater drawdown level. Fig. 15(a) shows that the 15m pore pressure at
 397 each monitoring point has basically approached zero, and the pore pressure at the center of the site has
 398 been less than zero, indicating that the groundwater level has fallen below this depth. Fig. 15(d) shows
 399 that the pore pressure at 30m first decreases and then increases and then decreases, which is obviously
 400 different from other depths. This is mainly because the buried depth of pore water pressure gauge pair
 401 has reached the confined aquifer, and the groundwater is mainly pumped from the deeper
 402 pressure-reducing wells outside the site. In the previous section, the single-well porous pumping test
 403 has proved that the confined aquifer recovers quickly and there is a certain source of replenishment.
 404 Therefore, after the pore pressure drops to a certain value, it basically stabilizes, and even slightly

405 increases. The rapid increase in pore pressure at 30 meters on June 3 was caused by the on-site
 406 decompression well stopping pumping. Fig.15 also shows the maximum pore pressure dissipation
 407 value at each point. It can be seen that the KY02 pore pressure dissipation value at the center of the
 408 well pipe with a 7m spacing is the largest, and its pore pressure dissipation value at 20m reaches
 409 160.9kPa.

410

413

4.5 CPTU test results

414

415

416

417

418

419

420

421

422

423

424

Before and after the treatment, the CPTU in-situ test was performed at the center of the site. The cone tip resistance q_c , side friction resistance f_s , and pore pressure u are measured as shown in Fig.16. The cone tip resistance q_c of the soil has been significantly increased after the treatment. Before treatment, q_c was between 0.2MPa~3MPa, with an average value of 1.09MPa. After treatment, it was increased to 0.5MPa~7MPa, with an average value of 1.83MPa. Especially in the depth of the water drawdown level in the range of 5~15m, q_c has a large increase of about 110%. And f_c has an increase of about 77.9%. It indicates that the bearing capacity of the foundation has increased significantly. Moreover, the pore water pressure u tested by CPTU has decreased, which is obvious. After treatment, it is 0 or close to 0 when the depth is above 15m. It is consistent with the field measurement results. It not only shows that the water in the upper part of the depth has been discharged by vacuum pumping, but also verifies the accuracy of the CPTU in-situ test results.

425

426

427

428

Based on the CPTU data and the empirical formula method, the undrained shear strength S_u and the compressive modulus E_s of the soil before and after the treatment can be estimated according to the measured cone tip resistance q_c , the specific calculation method is shown in Eq.(11)~Eq.(12). (Mayne and Kulhawy 1990; Xie et al. 2019).

429
$$S_u = \frac{q_c - \sigma_{v0}}{N_k}$$

430 (11)

431
$$E_s = a(q_c - \sigma_{v0})$$

432 (12)

433 Where, σ_{v0} is the total overburden pressure(kPa), and N_k is the empirical conic coefficient, with a
 434 value range of 11-19, taken as 16. a is the calculation coefficient. The range of a is 3~8 for most soft
 435 clay, taken as 3.5.

436 During the CPTU test, pore pressure dissipation tests at different depths were also carried out.
 437 According to the measured excess pore water pressure dissipation curve, Eq.(13) and Eq.(14) can be
 438 used to calculate the soil permeability coefficient k_h and consolidation coefficient c_h , and other
 439 important soil engineering property parameters (Chai et al. 2004).

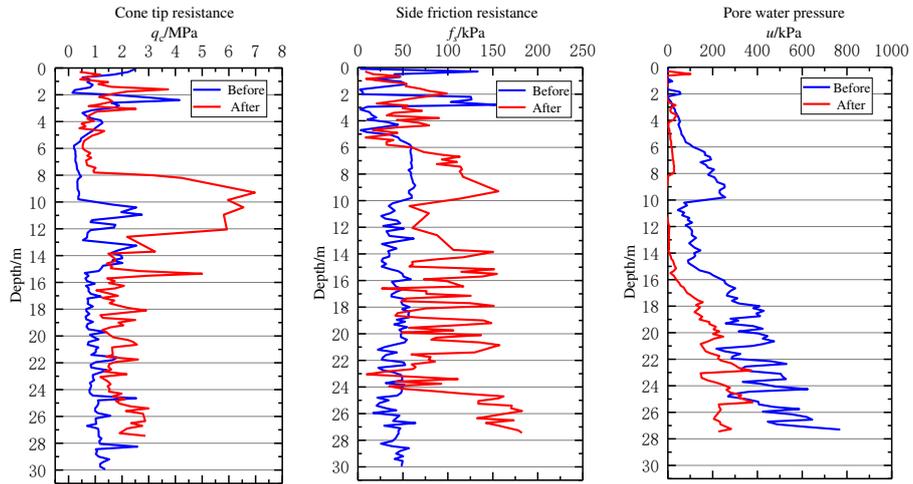

440
$$c_h = \frac{T^* \cdot r^2 \cdot \sqrt{I_r}}{t_{50}}$$

441 (13)

442
$$k_h = (251t_{50})^{-1.25}$$

443 (14)

444 Where, r is the probe radius, taking the value 17.85mm; I_r is the stiffness index, $I_r=G/S_u$, G is the shear
 445 modulus(kPa); t_{50} is the time when the over pore pressure dissipates to 50%, it can be checked on the
 446 drawn normalized over pore pressure curve(s). T^* is the time factor corresponding to t_{50} , taken as 0.245.

447
448 **Fig.16. CPTU test curve**

449 According to the CPTU test results, the main engineering parameters of the soil before and after the
 450 treatment are shown in Table 5. It can be seen that the undrained shear strength of each soil layer
 451 increased by 13.6%-193.9% after the treatment, especially the strength of the soft soil layer ③ and ④
 452 increased significantly; the compressive modulus increased by about 357.4%~515.1%, indicating that
 453 the compressibility of soil is small, the bearing performance of the foundation is enhanced; the

454 consolidation coefficient and the permeability coefficient is reduced. The vacuum tube-well has a
 455 significant effect of dewatering and consolidation.

456 **Table 5** Changes of main engineering parameters of soil before and after treatment

depth(m)	layer number	type of Soil layer	undrained shear strength S_u (kPa)		compression modulus E_s (MPa)		consolidation coefficient c_h ($10^{-3}\text{cm}^2/\text{s}$)		permeability coefficient k_h ($10^{-5}\text{cm}/\text{s}$)	
			before	after	before	after	before	after	before	after
			0~2.3	①	new fill	-	-	-	-	-
2.3~4	②	silty clay	103.4	117.52	4.77	14.49	-	-	-	-
4~10	③	sludge-Silty clay	24.27	150.07	3.2	19.81	2.11	0.49	0.84	0.019
10~15	④	silt sand-clay	101.03	261.39	13.33	34.50	-	-	-	-
15~30	⑤	sludge-Silty clay	51.86	155.34	6.84	20.51	-	-	-	-

457 Note: The soil layer classification in this table is based on CPTU test data, which is different from Table 1.

458 4.6 Settlement prediction

459 Prediction of final settlement is an important part of soft soil ground treatment. There are many
 460 methods for the calculation and prediction of ground settlement. According to its application principles,
 461 it can be basically divided into two categories. One is a purely theoretical calculation method based on
 462 the principle of soil consolidation and compression, such as layerwise summation method and
 463 numerical calculation method. And the other is a settlement prediction method based on measured
 464 settlement data, including the Asaoka method (Asaoka 1978), the hyperbola method (Sridharan et al.
 465 1981), and the logarithmic curve method (Zeng et al. 1981).

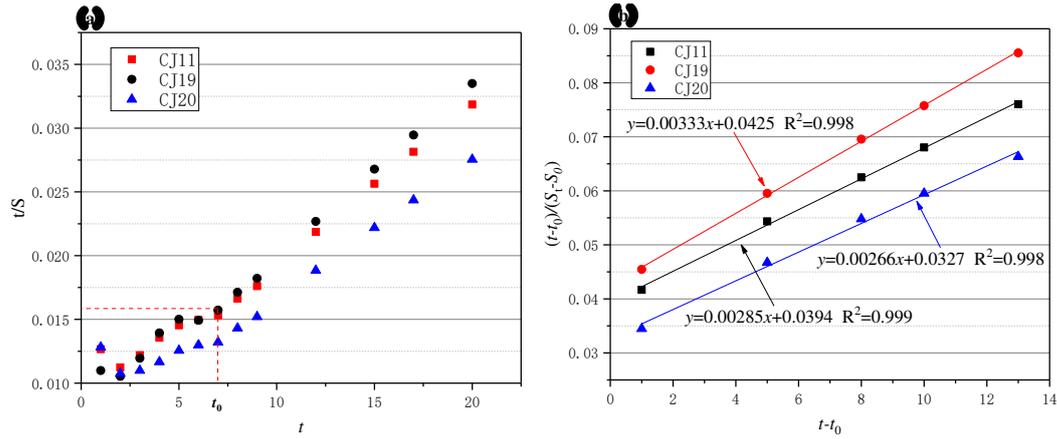

466 In this study, an empirical hyperbolic method introduced by Technical Specification for Vacuum
 467 Preloading Technique to Improve Soft Soils (Ministry of Transport of China 2009) was used to predict
 468 settlement. Assume that the total settlement of soils S_t consisted of two parts: Settlement of initial
 469 reference point (S_0) and the subsequent one, which can be fitted by the formula of the hyperbola. S_t can
 470 be calculated by Eq. (15).

$$471 \quad S_t = S_0 + \frac{t-t_0}{\alpha+\beta(t-t_0)} \quad (15)$$

474 When $t \rightarrow \infty$, the final settlement S_∞ can be calculated by Eq. (16).

$$475 \quad S_\infty = S_0 + \frac{1}{\beta} \quad (16)$$

477 Where, S_∞ is the settlement by dewatering and consolidation(m); S_0 and t_0 are initial reference point
 478 settlement and observation time(d). S_t is the settlement at time t. α and β are calculation parameters,
 479 which are the intercept and slope of the fitted curve, respectively.

480
481 **Fig.17** Settlement prediction curve(a) hyperbola of settlement and time; (b) fitting curve

482 Select the data of three representative settlement monitoring points for prediction, they are CJ11
483 (center), CJ19 (left) and CJ20 (right) respectively. According to the hyperbola of settlement and time
484 (Fig.17(a)), the settlement at $t_0=7$ can be used as the initial reference point S_0 . Perform linear fitting on
485 the settlement monitoring data after t_0 , and get the fitting curve as shown in Fig.17(b). According to the
486 fitting curve, the calculation parameters α and β are obtained and the final settlement of each
487 monitoring point is calculated as shown in Table 6. Comparing the settlement value measured in 20
488 days (S_{20}), the degree of consolidation(U) after the end of the pumping can be calculated. It can be seen
489 that the degree of consolidation of the three measuring points of CJ11, CJ19, and CJ20 are 76.5%,
490 79.1% and 80.1%, respectively. After 60 days of the test, the degree of consolidation of each
491 monitoring point is greater than 94%. Many scholars have introduced the cases of soft soil treatment by
492 vacuum preloading. The treatment time for most cases to reach the similar consolidation degree is more
493 than 100 days, and some cases even more than 300 days (Ding et al. 2019; Wu et al. 2020; Indraratna et
494 al. 2011). Therefore, the consolidation efficiency of vacuum tube-well dewatering technology has
495 obvious advantages.

496 **Table.6** Settlement prediction results of each monitoring point

monitoring point	S_0 (mm)	α	β	S_{∞} (mm)	S_{20} (mm)	U_{20} (%)	S_{60} (mm)	U_{60} (%)
CJ11	457	0.00285	0.00394	808	628	76.5	766	94.8
CJ19	455	0.00333	0.00425	755	597	79.1	714	94.6
CJ20	530	0.00266	0.00289	906	726	80.1	853	94.2

497 Note: S_{20} and S_{60} are the monitored settlement for 20 days and 60 days, respectively. U_{20} and U_{60} are the
498 corresponding degree of consolidation.

499 5 Conclusion

500 Preloading the deep soft soil in the Yangtze River floodplain with vacuum tube-well and conducting
501 some field monitoring tests. The following conclusions can be drawn from this paper.

502 Deep soft soil of the Yangtze River floodplain area in Nanjing has a special interlayer structure. The
503 clay layer is sandwiched with a thin layer of silt sand, and obvious horizontal thin bedding is formed,
504 which is similar to the horizontal drainage plate in the soil. This special structure provides favorable
505 conditions for the application of vacuum tube-well. However, in some clay layers with low
506 permeability coefficients, the application of this method may be limited.

507 Based on the single-well multi-hole pumping test, the hydraulic connection between the site aquifers
508 was found. The permeability coefficient, outflow and influence radius of the confined aquifer and

509 phreatic aquifer of the site were calculated by using the experimental observation data. Furthermore,
510 the layout of vacuum tube-wells and depressurization wells in a test site with 84m length and 84 width
511 was designed based on the above parameters.

512 Field test of vacuum tube-well dewatering technology was carried out on the test site . The results
513 showed that the surface subsidence and water drawdown level do not increase with the decrease of the
514 well pipe spacing due to the mutual interference of vacuum negative pressure. There is an optimal
515 spacing. In this test site, the 7m spacing has the best treatment effect. The settlement of the entire site
516 decreases radially from the center to the surrounding with 7m spacing wells. The settlement on the
517 right side of the test site (vacuum tube-well) is higher than that on the left side (no-vacuum tube-well),
518 indicating that the vacuum negative pressure can increase the pumping rate and the consolidation
519 effect.

520 The pore water pressure tested by CPTU is basically consistent with the field measured value. And
521 after treatment, the cone tip resistance q_c and side friction resistance f_s of the soil has been significantly
522 increased. Especially in the depth range where the groundwater drawdown levels, q_c and f_s increased by
523 about 110% and 77.49% respectively. It is indicated that the foundation bearing capacity was
524 significantly improved. Based on the CPTU pore pressure dissipation test, it was found that the
525 undrained shear strength S_u of the treated soil increased by 13.6%~193.9%, the compressive modulus
526 E_s increased by 357.4%~515.1%, and the engineering properties of the soil were significantly
527 improved.

528 Combined with the settlement monitoring data, the hyperbolic method was used to predict the final
529 settlement. The time required for vacuum tube-well dewatering technology to reach 94% degree of
530 consolidation is about 60 days, which is faster than the vacuum preloading method. Therefore,
531 consolidation efficiency of vacuum tube-well dewatering technology has obvious advantages.
