Abstract

Biodiesel is a renewable alternative fuel and glycerol as a main byproduct of the manufacturing process. Lipids could be produced from crude glycerol by using yeasts. The ability of 107 yeast strains to utilize glycerol was screened and 92 of these were selected. 60 strains were determined as a potential for lipid production by Sudan Black B staining. After secondary screening 25 of them showed specific growth rates (OD 600), high biomass production and lipid content. These strains were identified as *Pichia cactophila*, *P. fermentans*, *P. anomala*, *Rhodotorula mucilaginosa*, *R. dairenensis*, *Clavispora lusitaniae*, *Saccharomyces cerevisiae*, *Wickerhamomyces anomalus*, *Candida glabrata*, *C. inconspicua*, *C. albicans*, *Yarrowia lipolytica* with molecular identifications based on ITS and D1/D2 26S rDNA sequences. The results showed that *P. cactophila* accumulated lipid up to 64.94%, the highest lipid content. C16:0, C18:0, C18:1 and C18:2 essential fatty acids for biodiesel production were detected by GC-MS in the lipids accumulated by all strains. *P. cactophila* and *C. lusitaniae* were reported for the first time as lipid-producing yeasts. The results suggest that selected 25 isolates have the ability to grow on crude glycerol and especially *P. cactophila* produce lipid that has potential use as a feedstock for second generation biodiesel production.

Statement Of Novelty

In this study, two step screening was used for determining oleaginous yeasts which metabolize crude glycerol. Screening of new oleaginous microorganisms was important to find alternative sources of microorganisms to be used in biodiesel production. The 25 tested strains were potentially lipid-producer and generating more than 25.55% (wt/wt) lipids. Crude glycerol, a by-product of the biodiesel industry, was consumed mainly by *Pichia cactophila* and it was showed the highest yield (64.94%). Hence, the novelty of this study is for the first time *Pichia cactophila* and *Clavispora lusitaniae* being categorized as an oleaginous yeast. Palmitic, stearic, oleic and linoleic acid, essential fatty acids were produced by all strains.

Introduction

Biodiesel has attracted attention as an alternative and environmentally friendly fuel because of its low toxicity, biodegradability, and low concentrations of small particulate matter and SO₂ in exhaust gas when used in motor vehicles [1]. It is made from various vegetable oils or renewable biomass with short chain alcohol through transesterification. The oil raw material used for biodiesel production must absolutely compete with the food supply chain that brings food against the debate on biofuels versus food [2]. Biodiesel production is a process in which 10% crude glycerol is separated from the triacylglycerides in fats or vegetable oils [3].

Crude glycerol has some impurities such as methanol and potassium so crude glycerol processes limited value. Conversion of crude glycerol to specific products by chemical transformation may provide disadvantages such as low product specificity, high energy input and pretreatment requirements [4]. Crude glycerol has been employed as a substrate to obtain value added products such as 1,3-propanediol, lipids (SCO-single cell oils), citric acid, erythritol, succinic acid, butanol, ethanol, and hydrogen by bacteria, yeast, fungal or algal species [4, 5, 6].

Oleaginous microorganisms are known to accumulate lipids to more than 20 % of their total cell dry weight. Single cell oil (SCO) refers to the lipids produced by bacteria, yeasts, moulds and algae. Microorganisms meet the increasing oil demand for biodiesel production due to the structure similar to vegetable oils and fatty acid compositions. Microbial oil production has many positive factors such as short life cycle, less labor requirement, less space usage, no impact on climate change, low carbon dioxide emission, waste renewable biomass usage [7, 8]. Some oleaginous yeasts such as *Candida sp.*, *Rhodotorula sp.*, *Rhodospiridium sp.*, *Yarrowia sp.*, *Trichosporon sp.* and *Cryptococcus sp.* accumulate lipids to a level corresponding to 40 % of their biomass. However, during growth on nutrient-limited media such as fats, vegetable oils, and glycerol may accumulate lipids up to 70% of their biomass [6, 9, 10].

In recent years, interest in natural new yeasts isolated from different environments, has increased considerably in various biological production processes, including lipid production. Because they have important features such as genetic stability, environmental adaptation and special biotechnological attributes [11, 12, 13, 14]. Furthermore, the interesting results obtained with these wild-type yeasts in various fermentation processes suggest that screening studies with newly isolated yeasts are very important in terms of lipid production. There are several articles published in the past several years with focus on lipid accumulation from glycerol and crude glycerol by oleaginous yeasts but limited studies are available on comparative screening of newly isolated oleaginous yeast strains.

In this paper, two step screening of one hundred and seven yeast strains for the ability to grow and accumulate lipids in media containing glycerol as the sole carbon source were done. Twenty five yeast strains which grew the best were further tested for growth, biomass production, lipid content, fatty acid composition and identified molecular methods based on ITS and D1/D2 26S rDNA sequences.

Materials And Methods

Microorganisms

One hundred and seven yeast strains previously isolated from boza (which is a traditional fermented Turkish drink) were used in the study. For isolation of yeasts, Dichloran Rose Bengal Chloramphenicol Agar and Rose Bengal Chloramphenicol Agar (DRBCA, RBCA, Oxoid CM727, Basingstoke, UK) was used and incubated at 25 °C for 4–5 days [15]. The yeast strains were maintained on YPD agar slant [6] and stored at 4 °C before use.

Screening of oleaginous yeast

Two step screens were performed by using glycerol as the sole carbon source.

In the first screen, the yeast isolates were screened for their lipid-producing abilities on glycerol plates by qualitative analysis with the Sudan Black B staining technique [16]. The fresh yeast cultures were streaked onto glycerol plates [in g/L: peptone 20, yeast extract 20, commercial glycerol 30 (purity 85%) or crude glycerol 30]. After the petri dishes were incubated at 30 °C for two days, yeast isolates growing in both media or in crude glycerol medium were selected. Selected yeast cultures were stained with Sudan Black B technique. Prepared slides were observed under a phase contrast microscope on oil immersion. The presence of blue or greyish coloured fat globules within the cell was a positive result and the yeast strains showing that were selected for the second screen.

In the second screen, a loopful of cells from colonies on YPD agar plates were transferred to YPD broth (inoculum medium) and were incubated at 25 °C with shaking at 150 rpm for 72h. One mL of the prepared inoculum cultures was added to 20 mL of the medium containing 40 g/L crude glycerol, 20 g/L peptone, 20 g/L yeast extract and C/N ratio ~2,28. The mixtures were incubated for 72h at 25 °C with shaking at 150 rpm. Growth of the cultures were monitored by OD600 measurements of directly optical densities against the medium blank at 600 nm.

The best developing species were selected for cell dry weight, lipid content and fatty acid composition determination. Also, these species were identified. All chemicals used in the experiments were purchased from Merck Millipore.

Determination of yeast dry weight

Two mL of the cultures were centrifuged at 5000×g for 5 min. The pellet was washed twice with 5 mL of distilled water and dried at 60 °C until constant weight (typically 24 h). The dry cell weight was determined gravimetrically [17].

Extraction of lipid compounds

Total lipids were extracted from whole yeast cells by the method of Pan et al [17]. This is a fast procedure allowing complete lipid extraction. Briefly, 50-mL cell cultures were centrifuged at 5000×g for 5 min. The yeast pellets were washed twice with distilled water, then added into 10 mL of 4 M HCl, and incubated at 60 °C for 1 to 2 h. Then the acid-hydrolysed pellets were stirred with 20 mL of chloroform/methanol solution (1:1) at room temperature for 2 to 3 h. The mixtures were centrifuged at 2000×g for 5 min to separate the aqueous and organic phases. The lower phases containing lipids were recovered with a Pasteur pipette, and evaporated until dried. The dry lipid weight was determined gravimetrically [17].

Determination of glycerol concentration

The concentration of residual glycerol in the culture medium was analysed by high-performance liquid chromatography (HPLC), which was mainly equipped with a Bio-Rad Aminex HPX-87H column (300 mm × 7.8 mm), and a refractive index detector. The analytical column was operated at 60°C with 0.2 µm filtered 0.005 M H₂SO₄ solution as the mobile phase. The mobile phase flow rate was 0.6 ml/min [18].

Fatty acid composition determination

Fatty acid compositions of oil samples were determined using a modified fatty acid methyl esters (FAME) method. The oil extracts obtained were transmethyalted to FAME by heating (90°C for 45 min) with a mixture of 35% (vol/vol) BF₃/MeOH (12% BF₃/ MeOH), 45% (vol/vol) MeOH, and 29% (vol/vol) hexane [16]. The FAME was then analyzed by GC/MS (Agilent 7820A/5977EMSD). The system was equipped with an autosampler and an MS detector. Helium was used as the carrier gas. The FAME were separated on a capillary column (100 m × 0.20 mm, HP-88, Agilent J&W Column) with the film thickness of 0.25 µm. The detector temperature was set at 230°C. Initial column temperature was 120°C for 1 min and increased to 175°C at the rate of 10°C/min, held at 175°C for 10 min, then increased to 210°C at the rate of 5°C/min held at 210°C for 5 min. and then increased to 230°C at the rate of 5°C/min and held for 10 min [19].

Molecular identification

Molecular characterization of yeasts, cultures were grown on Yeast Extract Agar prior to DNA extraction. DNAs were isolated by using GE Healthcare genomic DNA purification kit and used for PCR amplification. Internal Transcribed Spacer (ITS-1, 5.8S and ITS-2) regions of the rDNA genes and D1/D2 domain of the 26S rDNA genes which were the standard gene regions for molecular identification were amplified by using primers NL1 (5'-GCATATCAATAAGCGGAGGAAAAG-3') and NL4 (5'-GGTCCGTGTTTCAAGAGG-3') for D1/D2 region [20] and primers ITS1 (5'-TCCGTAGGTGAACCTGCGG-3') and ITS4 (5'-GCATATCAATAAGCGGAGGA-3') for ITS region [21]. Then they were sequenced by CEQ 8000 Genetic Analysis System. Obtained sequences in this study were compared with those deposited in the National Center for Biotechnology Information (NCBI) Database by BLAST for identification. The ITS and D1/D2 region sequences of identified yeasts were submitted to GenBank for accession numbers.

Result And Discussion

Screening

One hundred and seven yeast strains previously isolated from boza were tested in YPD medium using commercial glycerol or crude glycerol as carbon source. It was determined that crude glycerol, provided by a private waste oil collection company, showed the following properties: pH 6.9 and purity 70.775 %. Ninety-two strains which could be growing both of the medium or only crude glycerol medium were stained with Sudan black B technique and observed under microscope for the presence of fat globules within the cell. Sixty yeast strains were found positive for showing fat globules within the cell (Fig. 1) and they were selected as potential lipid biomass producers (Table 1). It has been demonstrated that Sudan black B staining technique is a rapid method of screening lipid production. In their work Kitcha and Cheirsilp [16] were determined rapidly whether 889 yeast strains had lipid production ability by Sudan black B technique and they have revealed that 23 isolates are potential lipid producers.

Table 1
Growth on commercial/crude glycerol and results of staining

Carbon source	Number of yeast strains		
	Growth	Sudan black B staining	
		+	-
Crude glycerol	1	1	
Crude glycerol and commercial glycerol	91	59	32
Commercial glycerol	6	no staining	no staining

In the first screening, we performed lipid screening on both crude glycerol and commercial glycerol medium. In the experiments, two separate glycerol's were used to see the differences in metabolizing the crude and commercial glycerol of microorganisms. In general, 107 isolates grew on both glycerol media. Only 6 of them did not grow in crude glycerol and 9 of them did not grow in both (Table 1). Similar to our work previously shown that crude glycerol is a useful waste substrate for lipid production by *Yarrowia lipolytica* [22, 23] and some other yeasts [5].

Results of the secondary screening, summarized in Fig. 2, show the final OD600 values of the 60 yeasts in a medium containing crude glycerol as carbon source (40 g/l). Between the 60 yeast strains tested, 25 grew well and reached final OD600 of nearly 2 Units or up. They were selected for calculation of growth parameters and lipid yield. Good performance was exhibited by isolate 4 that reached final OD600 of 2.74 on the other hand isolate 37 grew most poorly (Fig. 2). Many researches have been done on the microbial conversion of crude glycerol. However, impurities in crude glycerol often negatively affected the success of these processes [24]. Since we are working with a crude glycerol containing higher impurities (purity 70.775 %) than various publications (14, 22, 23; 25), the selection was made among the isolates by looking at their ability to metabolize crude glycerol in the screening step. Also, in microbial lipid production studies, ~ 20–100 C/N ratio has been used because it is known that high C/N ratio promotes lipid production in some yeast species [14, 22, 23, 26]. On the other hand, as we mentioned above, the crude glycerol we used has high impurities for this reason a second stress factor affecting growth due to low nitrogen ratio was not used.

Calculation Of Lipid Yield Parameters And Biomass

Among 25 isolates, four of them (1, 4, 6 and 18) gave high lipid yield with lipid content higher 55% when grown in broth medium containing crude glycerol for 72h. Table 2 shows biomass and lipid yield parameters of all strains. The lowest amount of lipid yield obtained from 25 yeast isolates selected by first-screening (25, 55%) was indicative of the accuracy of the pre-screening. It was determined that isolate 1 gave highest lipid content and highest lipid yield up to 64.94% and 7.14 g/L, respectively (11 mg/mL of biomass). High lipid accumulation and also high lipid coefficient in crude glycerol media, isolate 1 was selected for the further studies.

Table 2

After 72 hours of incubation, the analysis of residual crude glycerol is performed for calculation of lipid coefficient. Yeast isolates were not utilized glycerol completely. It was thought that the accumulated lipids in the yeast cells were not used for lipid-free biomass synthesis because yeasts do not use their stored lipids before the run out of extracellular carbon supply [27, 28, 29].

For indicating further availability of using strains selected in this study for single cell oil production from crude glycerol, lipid production results of this study were compared with other oleaginous microorganisms using crude glycerol as the sole carbon source. The biomass, lipid content and lipid yield of *Yarrowia lipolytica* ATCC 20460 after fermentation were 11.6 g/L, 31% and 3.6 g/L, respectively [30]. The biomass, lipid content and lipid yield of *Cryptococcus curvatus* ATCC 20509 after fermentation were 29.2 g/L, 26.0% and 7.7 g/L, respectively [31]. The biomass, lipid content and lipid yield of *Kodamaea ohmeri* BY4-523 and *Trichosporanoides spathulata* JU4-57 after fermentation were 10.3 g/L, 53.0%, 5.5 g/L and 17.0 g/L, 43%, 7.4 g/L, respectively [32]. The biomass, lipid content, lipid yield and lipid coefficient of *Rhodotorula glutinis* TISTR 5159 were 8.17 g/L, 53%, 4.3 g/L, and 7%, respectively [33]. The biomass, lipid content, lipid yield and lipid coefficient of *Mortierella isabellina* were 6.2 g/L, 53%, 3.3 g/L and 12% respectively [34]. The biomass, lipid content, lipid yield, and lipid coefficient of *Trichosporon fermentans* and *Trichosporon cutaneum* after 8-day fermentation were 16.0 g/L, 32.4%, 5.2 g/L, 16.5%, and 17.4 g/L, 32.2%, 5.6 g/L, 17.0%, respectively [35]. Maximum lipid content of lipid-engineered *Yarrowia lipolytica* strain JMY4086 after continuous culture with molasses and crude glycerol under different oxygenation conditions was 31% [23]. Biomass and lipid yield parameters of selected 25 isolates in this study by two step screening were moderate or higher than strains above, exhibiting that strains in current study were encouraging strains for single cell oil production using crude glycerol as the sole carbon source.

Fatty Acid Compositions

Lipid samples produced by fermentation on crude glycerol were analysed by GC/MS. Percentages of total fatty acids were shown in Table 3. The fatty acid contents of fatty yeasts are generally known to consist of long chain fatty acids such as C16 and C18 [36]. Lipids of selected 25 oleaginous fungi were composed mainly of long-chain fatty acids with 16 and 18 carbon atoms. Main fatty acids of microbial lipids are an important indicator that whether it can be used for biodiesel production. For the quality of biodiesel and optimum fuel properties Fatty acid composition is quite important. Increasing the chain length

of fatty acids increases the cetane number, combustion temperature, melting point and viscosity of clean oil compounds of biodiesel. Furthermore, the high amount of oleic acid in fatty acid content has a positive effect on biodiesel properties [36]. Presence of C16:0, C18:0, C18:1 and C18:2 fatty acids were detected by GC-MS. FAME analysis of yeast strains are relevant from a biodiesel standpoint and also to discriminate closely related strains. The total unsaturated fatty acids, oleic acid and linoleic acid similar to that of plant oils were > 50 % of microbial oils except isolate 7. Knothe [37] was reported that the best fatty acid composition for biodiesel production is palmitic acid (C16:0), stearic acid (C18:0), oleic acid (C18:1), linoleic acid (C18:2) and linolenic acid (C18:3). This indicates that lipids from oleaginous yeasts selected in this study have potential use as a feedstock for second generation biodiesel production. These fatty acids were reported by Kumar et al. for lipid production from municipal waste in the glycerol medium, and they also concluded that these fatty acids are suitable for biodiesel production [25].

The predominant fatty acid in the lipid from isolate 1 that gave highest lipid content and highest lipid yield on crude glycerol was stearic acid (36,82%) followed by linoleic acid (33.72 %), oleic acid (17.51 %), and palmitic acid (11.95 %). The results of fatty acid analysis after lipid production and optimization studies with *Rhodotorula sp.* [38], *Psuedozyma sp.* [1] were similar to ours. Areesirisuk et al. [1] were also remarked that these fatty acid profiles were the same as the vegetable oils used in biodiesel production and fatty acid profiles of some oleaginous yeasts, and also that the fatty acid composition used in biodiesel production affected biodiesel quality.

Identification Of Oleaginous Yeasts

The 25 oleaginous yeast isolates that selected by screening in the glycerol medium were identified by the molecular diagnosis methods based on sequencing of the ITS region of the rDNA and D1/D2 regions of 26 S of the rDNA. Results showed high sequence similarity (98–99%) with strains in the GenBank. The

GenBank accession numbers of the ITS and D1/D2 regions of strains sequenced in this study are given in Table 4. 25 isolates were identified as 13 different strains (Table 4). Isolate 7 and 26 could not be identified, they might be new strains. Two of strains were reported for the first time as lipid-producing yeast, because no information on lipid production of *Pichia cactophila* and *Clavispora lusitaniae* was found in the literature. The results of this study have been shown that there were plentiful new microorganism resources which produce lipids by using glycerol as sole carbon source.

Conclusion

In this study two step screening was used for determining oleaginous yeasts which metabolize crude glycerol as the sole carbon source from newly isolated strains. The 25 tested strains were able to grow and consume the crude glycerol. Moreover, they were potentially lipid-producers and generating more than 25.55% (wt/wt) lipids. These results indicated the correctness of the screening process. Crude glycerol, a by-product of the biodiesel industry, was consumed mainly by *Pichia cactophila* (isolate 1), *Rhodotorula mucilaginosa* (isolate 6) and *Pichia fermentans* (isolate 4 and 18) showed the highest lipid production [more than 55% (wt/wt)]. *P. cactophila* was showed the highest yield (64.94%).

This is the first report of *Pichia cactophila* and *Clavispora lusitanae* being categorized as an oleaginous yeast. Palmitic acid, stearic acid, oleic acid and linoleic acid, essential fatty acids for biodiesel production, were produced by all strains. Similar composition of fatty acids made it competitive with biodiesel production from other sources.

The screening, identification and characterization of potential productive oleaginous yeasts were the initial stage of microbial biodiesel production. All the results obtained from this study it was found that screening of new oleaginous microorganisms was important to find alternative sources of microorganisms to be used in biodiesel production and yeasts could be one of the most feasible and practicable sources for biodiesel production.

Figures

Figure 1

Ninety-two strains which could be growing both of the medium or only crude glycerol medium were stained with Sudan black B technique and observed under microscope for the presence of fat globules within the cell. Sixty yeast strains were found positive for showing fat globules within the cell

Figure 2

Between the 60 yeast strains tested, 25 grew well and reached final OD600 of nearly 2 Units or up. They were selected for calculation of growth parameters and lipid yield. Good performance was exhibited by isolate 4 that reached final OD600 of 2.74 on the other hand isolate 37 grew most poorly
