Abstract

MicroRNAs (miRNAs) have been extensively studied as non-invasive biomarkers for cancer diagnosis and prognosis, while the clinical application was constrained by the heterogeneous miRNA sources in plasma and the tedious assay processes. Here we developed a one-pot assay called dual-Surface-protein-guided Orthogonal Recognition of Tumor-derived Exosomes and in-situ profiling of microRNAs (SORTER) for rapid and precise diagnosis of prostate cancer. The SORTER utilizes the orthogonal barcoding of two allosteric aptamers against exosomal marker CD63 and tumor marker EpCAM to recognize and sort tumor-derived exosome subtypes. Furthermore, the labeled barcode on tumor-derived exosomes guided the targeted fusion with liposome miRNA detection probes, enabling in-situ profiling of tumor-derived exosomal miRNAs. With a signature of six miRNAs, SORTER differentiated prostate cancer and benign prostatic hyperplasia with a sensitivity, specificity, and accuracy of 100% in the training and validation cohorts. The SORTER provides a promising tool to advance the clinical adaptability of miRNA-based liquid biopsy.

Introduction

MicroRNAs (miRNAs) are a class of short non-coding single-stranded RNAs (approximately 22 nucleotides) that play fundamental roles in gene expression regulation by repressing the translation of target genes or degrading their target transcripts[1, 2]. Dysregulated miRNAs are closely associated with the pathogenesis of a variety of cancers and thus have been studied as emerging biomarkers in cancer diagnosis, prognosis, and treatment monitoring[3, 4]. However, the clinical value of miRNAs in liquid biopsy was questioned by researchers, attributed to the heterogenous origins and existing forms of miRNAs in bodily fluids, such as circulating free miRNAs, miRNAs bounded with ribonucleoproteins, or encapsulated in different extracellular vesicles[5, 6]. The non-specific source of biomarkers diminishes the accuracy of miRNAs as a diagnostic tool and has become the stumbling block to moving from proof-of-concept to clinical application. Exosomes are a unique subtype of extracellular vesicles generated via endosomes and multivesicular bodies pathway[7, 8]. miRNAs are selectively packed and enriched in exosomes as regulators of a wide range of physiologic and pathologic processes, and keep stable under the protection of lipid membranes[9, 10]. In particular, tumor-derived exosomal miRNAs are closely associated with cancer progression[11] and afford great promise to enhance the specificity and accuracy of miRNA-based liquid biopsy. Unfortunately, the specific recognition of tumor-derived exosomes and quantitative detection of exosomal miRNAs are still technically challenging due to the complex background interference[12-14], heterogenous EV subtypes[15, 16], and varied expression levels of different exosomal miRNAs[17, 18]. In addition, the existing miRNA assays require multiple manual steps and take a long assay time. Therefore, developing a sensitive, accurate, and simplified bioassay to quantify tumor-derived exosomal miRNAs in complicated biofluid samples is highly desirable to promote the development of clinically viable miRNA biomarkers of cancer.

The prevailing RNA quantification technologies, such as quantitative reverse transcription-polymerase chain reaction (qRT-PCR) and next-generation sequencing (NGS), enable the detection of specific miRNA species in exosomes with high sensitivity down to fM[18, 19]. However, these technologies necessitate a large sample volume (> 500 μL) to obtain sufficient exosomes for RNA analysis and involve exosome concentration, RNA extraction, cDNA generation, and sequence amplification procedures[20, 21], which are laborious and time-consuming. Moreover, the analysis is susceptible to interference of free miRNAs in

56 biofluids, whose abundance is several orders higher than exosomal miRNAs[22-24]. Alternative to the sequence

57 amplification-based strategies, a series of in-situ exosomal miRNAs bioassays have been recently developed

58 by directly or indirectly importing DNA probes into membrane vesicles, such as gold nanoflares (Au NFs)

59 and molecular beacons (MBs)[25-27]. Zhou et al. designed a virus-mimicking fusogenic vesicle-encapsulated

60 MBs probe, which can rapidly detect extracellular vesicle miRNAs within 2 h via membrane fusion[28]. Zhao

61 et al. proposed a thermophoretic sensor for in-situ extracellular vesicle miRNAs analysis by transporting Au

62 NFs into vesicles, showing detection sensitivity down to 0.36 fM in 0.5 μL plasma samples[29]. These in-situ

63 technologies provided efficient and robust extracellular vesicle miRNA detection without resorting to tedious

64 RNA extraction and eliminated the background interference of complex biofluid samples. However, the

65 transportation of miRNA probes into vesicles is stochastic and cannot distinguish tumor-derived exosomes

66 from other non-specific vesicles. The ensemble detection of total EV miRNAs conceals the specificity of

67 tumor-derived exosomal miRNA and reduces the accuracy in liquid biopsy applications.

68 Tumor-derived exosomes only account for a small fraction of EVs, thus challenging to distinguish them

69 from other EVs precisely[30]. Surface protein receptors are routinely used to identify the unique subtype of

70 various extracellular vesicles[12, 31]. Typically, the tetraspanin CD63 is often enriched in exosomes compared

71 with other vesicles[32], and epithelial cell adhesion molecule (EpCAM) is a typical marker of tumor[33]. The

72 orthogonal combination of the two proteins sets a more critical threshold and holds great promise in

73 recognizing and sorting tumor-derived exosomes. A multi-receptor-based DNA logic device has recently

74 been reported to bindle multiple aptamers into a single computing device and recognizes subpopulations of

75 cells and exosomes[34-36]. For instance, Chuang et al. developed an AND Boolean logical device using multiple

76 aptamers and toehold activation for signal integration and amplification to label and recognize target cell

77 types via the synergistic presence of different surface protein receptors[37]. Our group reported that the dual-

78 surface-protein-aptamer recognition combined with droplet digital PCR achieved the quantitative profiling

79 of tumor-derived exosomal PD-L1[38]. However, to the best of our knowledge, this multiple protein receptors

80 synergistic logic device has not been utilized in the selective recognition and sorting of exosome subtypes.

81 Addressing these challenges, here we developed dual-Surface-protein-guided Orthogonal Recognition

82 of Tumor-derived Exosomes and in-situ probing of microRNA profiles (SORTER) for rapid and specific

83 detection of tumor-derived exosomal miRNAs. The SORTER affords three significant advantages over the

84 existing exosomal miRNA biosensing assays. Firstly, the SORTER presents the first strategy to recognize

85 and sort tumor-derived exosomes precisely, a small yet considerable subpopulation of extracellular vesicles,

86 improving the diagnostic and prognostic accuracy of exosome-based liquid biopsy. Specifically, dual

87 allosteric aptamers of exosome-specific marker CD63 and tumor marker EpCAM were employed to create

88 a unique orthogonal identity barcode on tumor-derived exosomes, thus inducing the targeted recognition and

89 controlled fusion of miRNA probes for signal amplification. Second, the in-situ miRNA detection inside the

90 membrane structures of exosomes prevents the contamination of free circulation miRNAs and degradation

91 of RNases from biofluid samples, enabling the accurate quantification and even dynamic monitoring of

92 tumor-derived exosomal miRNAs. Third, we incorporate multiple processes into SORTER, such as exosome

93 recognition, importing probes, miRNA signal transduction, and amplification, and create a separation- and

94 washing-free tumor-derived exosomal miRNAs assay. The SORTER offers superior analytical performance

95 towards liquid biopsy applications, which consumes only 0.2 μL plasma sample and completes the whole

96 analysis in less than 2 h. We tested an exosome signature of six miRNAs (miR-222, miR-1290, miR-182,

97 miR-21, miR-221, and miR-10b) in the training ($n = 42$) and validation ($n = 32$) cohorts, which can

98 differentiate prostate cancer (PCa) and benign prostatic hyperplasia (BPH) with a sensitivity, specificity, and

99 accuracy of 100%. The diagnostic accuracy also reached 90.6% in classification of metastatic and non-

100 metastatic prostate cancer. We envisioned that the SORTER provides a promising tool to advance the analysis

101 of tumor-derived exosomal miRNAs and promote the clinical adaptability of miRNA-based liquid biopsy.

Results

103 **Working principle of SORTER**.

104 The SORTER assay is designed to achieve specific recognition and sorting of tumor-derived exosome

105 subtypes and in-situ sensitive probing of tumor-derived exosomal miRNA profiles, and further improve the

106 miRNA-based diagnostic accuracy of prostate cancer. The whole workflow consists of six steps as shown in

107 Fig.1, including sample collection, plasma preparation, barcode labeling of tumor-derived exosomes,

108 targeted importation of miRNA detection probes, in-situ multiplexed miRNA profiling, and biostatistical

109 analysis for cancer diagnosis. The streamlined processes are highly straightforward and thus enable the rapid

110 and precise one-pot miRNA profiling in tumor-derived exosomes. The two significant innovations of

SORTER are: (i) selective labeling and sorting of tumor-derived exosomes through dual-surface-protein-guided orthogonal recognition, and (ii) in-situ sensitive quantification of miRNAs via duplex-specific nuclease (DSN) catalyzed signal amplification.
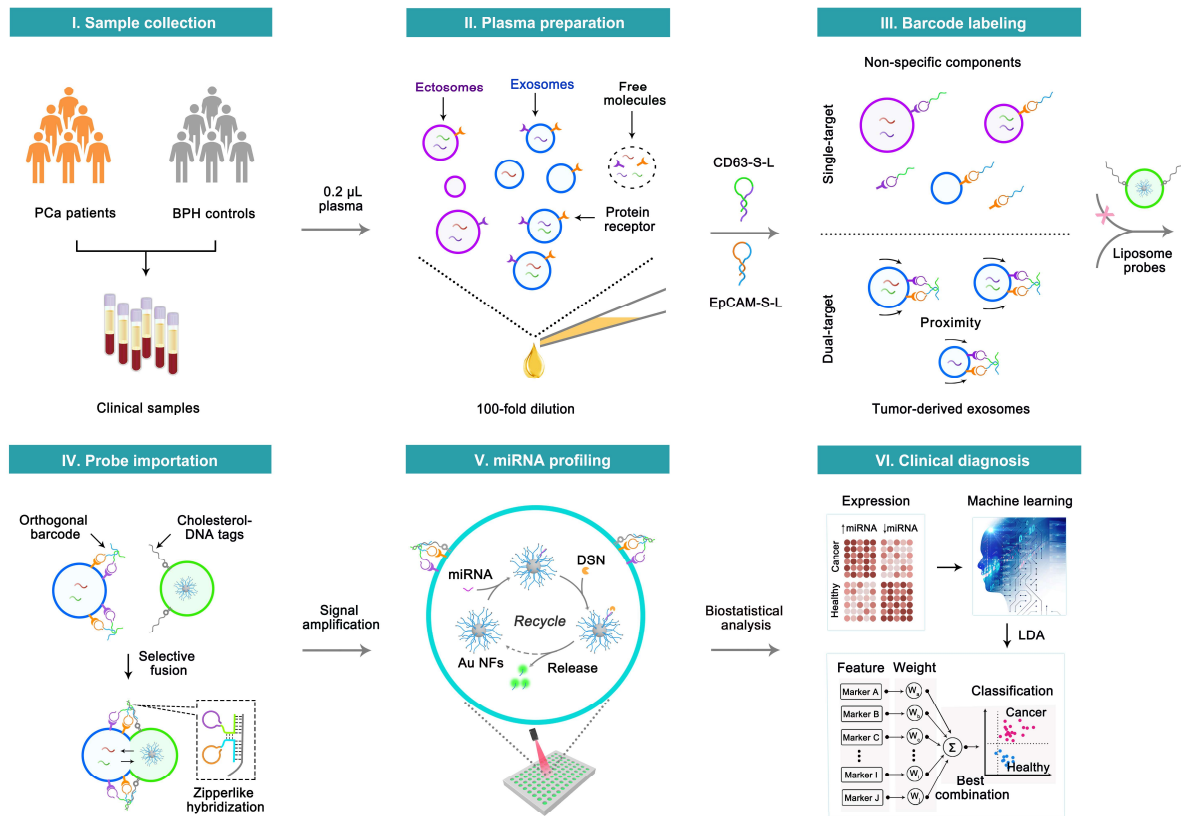

Fig. 1 Schematic illustration of SORTER assay for miRNA profiling of tumor-derived exosomes. I-II) Clinical plasma samples (0.2 μL) were collected from age-matched prostate cancer (PCa) patients and benign prostatic hyperplasia (BPH) controls. Exosomes, ectosomes, and free molecules produced by tumor and normal cells coexist in plasma samples and exhibit overlapping compositional features. **III**) Dual-surface-protein-guided orthogonal recognition barcode for the selective labeling of tumor-derived exosomes. The two allosteric aptamer probes (CD63-S-L and EpCAM-S-L) consist of three domains: the aptamer (CD63 or EpCAM) domain, the spacer (S) domain, and the linker (L) domain. The allosteric aptamer probes are in a non-active state with a hairpin structure, where the L domains are blocked for the subsequent reaction. When two protein receptors, CD63 and EpCAM, are recognized synergistically on a single exosome, two distinct L domains are exposed by allosteric transformation, creating a unique orthogonal barcode on tumor-derived exosomes via proximity-induced self-assembly. **IV**) The importation of miRNA detection probes into tumor-derived exosomes. The labeled barcode hybridized with complementary DNA tags anchored on liposome probes in a zipper-like behavior, bringing the bilayers into contact and facilitating membrane fusion to import miRNA detection reagents. **V**) Multiparametric assessment of miRNA profiles in tumor-derived exosomes. The SORTER incorporates multiple processes, including exosome recognition, importing probes, signal transduction, and amplification, permitting a sensitive and robust one-pot tumor-derived exosomal miRNAs assay. **VI**) The data processing and bioinformatic analysis for cancer diagnosis. The linear discriminant analysis (LDA) algorithm is used to identify the best combinations of miRNAs to classify PCa patients from BPH controls, and the LDA model then evaluates the predicted results.

132   There is no specific single marker to distinguish the heterogeneous sources of miRNAs in plasma

133   selectively. In plasma samples, for example, tumor- and normal-derived exosomes, ectosomes, and free

134   molecules (e.g., RNA-protein complexes) coexist and have overlapping compositional properties. Therefore,

135   we leverage the combination of two typical surface protein markers, CD63 for exosomal-specific markers

136   and EpCAM for the tumor-specific marker, to set up an orthogonal screening threshold and recognize tumor-

137   derived exosomes from complicated biofluid samples precisely. Aptamers are promising tools for protein

138   labeling because of their excellent specificity and affinity, low production costs, and configurational

139   programmability[39-41]. We designed two allosteric aptamer probes of CD63 and EpCAM (detailed in

140   Supplementary Fig. S1) as input units for orthogonal labeling of the tumor-derived exosome in clinical

141   samples. The synergetic recognition of CD63 and EpCAM on a single exosome will trigger the allosteric

142   transformation of aptamer probes, thus creating a unique orthogonal identity barcode on the tumor-derived

143   exosome's surface via proximity-induced self-assembly. In particular, the unbounded aptamer probes are still

144   in a non-active state, thus there is no need to wash away excess probes. The dual-target-protein-guided

145   orthogonal barcoding method permits the rapid and selective labeling of tumor-derived exosomes in clinical

146   samples, avoiding lengthy pre-isolation/purification processes and minimizing the non-specific interference

147   of contaminated vesicles.

148   The quantification of tumor-derived exosomal miRNAs faces two major challenges: (i) the amount of

149   circulating free miRNAs in the blood is several orders of magnitude more than target miRNAs in tumor-

150   derived exosomes and cause serious interference to detection[15, 16, 42]; (ii) the concentration of miRNAs in

151   tumor-derived exosomes is extremely low (approximately 1 copy/10^6 EVs to 1 copy/1 EV)[22-24], thus a

152   superior sensitive assay is required for miRNA profiling. To address these issues, we designed a smart

153   liposome probe (Tags-Lipo@Au NFs) to import miRNA detection probes into tumor-derived exosomes via

154   targeted vesicle fusion and achieve in-situ sensitive quantification of various miRNAs inside exosomes. We

155   utilized the orthogonal barcode on tumor-derived exosomes (Orth-Exo) to hybridize with complementary

156   DNA tags anchored on liposome probes (Tags-Lipo@Au NFs), facilitating the selective recognition of

157   tumor-derived exosomes and the simultaneous importation of miRNA detection probes. After that, the

158   fluorescent signal of miRNAs was then generated and amplified using gold nanoflares (Au NFs) and duplex-

159   specific nuclease (DSN) encapsulated in liposome probes. Specifically, the Au NFs were prepared by

160 immobilizing recognition sequences (5'-labeled-SH and 3'-labeled-FAM) onto spherical Au nanoparticles,

161 where the fluorescence is effectively quenched by the Au surface, significantly minimizing the background

162 signal. The target miRNA will bind with the DNA probe in the nanoflares to form DNA-RNA heteroduplexes.

163 Notably, the DNA sequence in DNA-RNA heteroduplexes will be cleaved specifically by DSN to release

164 fluorophore for fluorescence and RNA sequence, and initiate the target recycling and signal amplification

165 process. The in-situ miRNA assay inside the membrane structures of exosomes eliminates the interference

166 of circulating free miRNAs, and the Tags-Lipo@Au NFs probes provide the minimized background and

167 amplified fluorescent signal, thus enabling highly selective and sensitive quantification of target miRNAs in

168 tumor-derived exosomes.

169 **Dual-surface-protein orthogonal barcode labeling on tumor-derived exosomes.**

170 We selected a panel of nine membrane protein markers as candidates to distinguish the tumor and

171 normal cell-derived exosomes: one exosome protein marker (CD63) and eight tumor protein markers,

172 including EpCAM, nucleolin (NCL), carcinoembryonic antigen (CEA), human epidermal growth factor

173 receptor 2 (HER2), mucin 1 (MUC1), programmed cell death 1 ligand 1 (PD-L1), prostate-specific

174 membrane antigen (PSMA) and protein tyrosine kinase 7 (PTK7). Prostate cancer cell (LNCaP, PC-3) and

175 benign prostatic hyperplasia cell (BPH-1)-derived exosomes (Exo) were used as the models of tumor-derived

176 and normal-derived exosomes. The corresponding FAM-labeled aptamer probes (Supplementary Table S1)

177 bind with the target proteins on the exosomes (Supplementary Fig. S2a), respectively. Flow cytometry

178 analysis of LNCaP Exo and PC-3 Exo (Supplementary Fig. S2b-c) presents the highest expression level of

179 EpCAM compared to the other seven tumor markers and indicates the best performance to distinguish tumor-

180 derived exosomes (LNCaP, PC-3) from normal-derived exosomes (BPH-1). Therefore, the synergistic

181 identification of target proteins CD63 (exosome marker) and EpCAM (tumor marker) is the best choice for

182 recognizing and sorting tumor-derived exosomes.

183 To rapidly and selectively label tumor-derived exosomes with a traceable barcode in complex clinical

184 scenarios, we design two allosteric aptamer probes of CD63 and EpCAM proteins as input units for

185 orthogonal labeling of the tumor-derived exosome. The allosteric aptamer probes (CD63-S-L or EpCAM-S-

186 L) consist of three domains: the aptamer (CD63 or EpCAM) domain, the spacer (S) domain, and the linker

187 (L) domain. The allosteric aptamer probes are in their non-active configuration with a hairpin structure, and

188   the L domain is annealed and blocked for the downstream reaction. The aptamer domain of allosteric probes

189   can specifically recognize the target proteins, exposing the L domain by allosteric transformation. To confirm

190   whether CD63-S-L and EpCAM-S-L bind to target proteins and expose the L domain, we performed

191   fluorescence kinetic analysis on LNCaP Exo using fluorescence resonance energy transfer (FRET) couple

192   (BHQ1 and FAM) double-labeled CD63-S-L and EpCAM-S-L (Supplementary Fig. S3a-b). This allowed us

193   to easily monitor the allosteric transformation reaction through an increase in the fluorescence signal. When

194   the two allosteric aptamer probes of CD63-S-L or EpCAM-S-L were incubated with LNCaP Exo, the

195   fluorescence signal increased significantly, while almost no signal changes were observed in the control

196   experiments (CD63-S-L or EpCAM-S-L only). These findings validated that the designed allosteric aptamer

197   probes of CD63-S-L or EpCAM-S-L can bind to target proteins of exosomes efficiently and trigger an

198   allosteric change to expose the L domain, allowing the orthogonal barcode labeling of tumor-derived

199   exosomes.

200   To confirm whether CD63 and EpCAM are co-expressed on a single tumor-derived exosome surface,

201   we utilized a total internal reflection fluorescent microscope (TIRFM) to image CD63-S-L (3'-labeled-FAM)

202   and EpCAM-S-L (5'-labeled-Cy5) double-labeled tumor LNCaP Exo and normal BPH-1 Exo. Fig. 2a

203   illustrated CD63-S-L (FAM) and EpCAM-S-L (Cy5)-mediated orthogonal labeling on a single exosome

204   surface. Substantially strong fluorescent signals of CD63 (green dot) and EpCAM (red dot) were collocated

205   on the same particles of LNCaP Exo (orange dot in merged images), while very little colocation fluorescent

206   signals were detected from BPH-1 Exo (Fig. 2b). We further checked the labeling efficiencies of CD63-S-L

207   (FAM) and EpCAM-S-L (Cy5) on LNCaP Exo and BPH-1 Exo by flow cytometry (Fig. 2c). It was observed

208   that EpCAM-S-L (Cy5) has a substantially higher labeling efficiency on LNCaP Exo (10.6%) than BPH-1

209   Exo (0.73%), while CD63-S-L (FAM) has a better labeling efficiency on LNCaP Exo (1.23%) than BPH-1

210   Exo (0.23%). These findings show that CD63 and EpCAM proteins are expressed and coexist on a single

211   tumor-derived exosome surface and that CD63 and EpCAM probes can be effectively labeled on the same

212   vesicle surface.

213
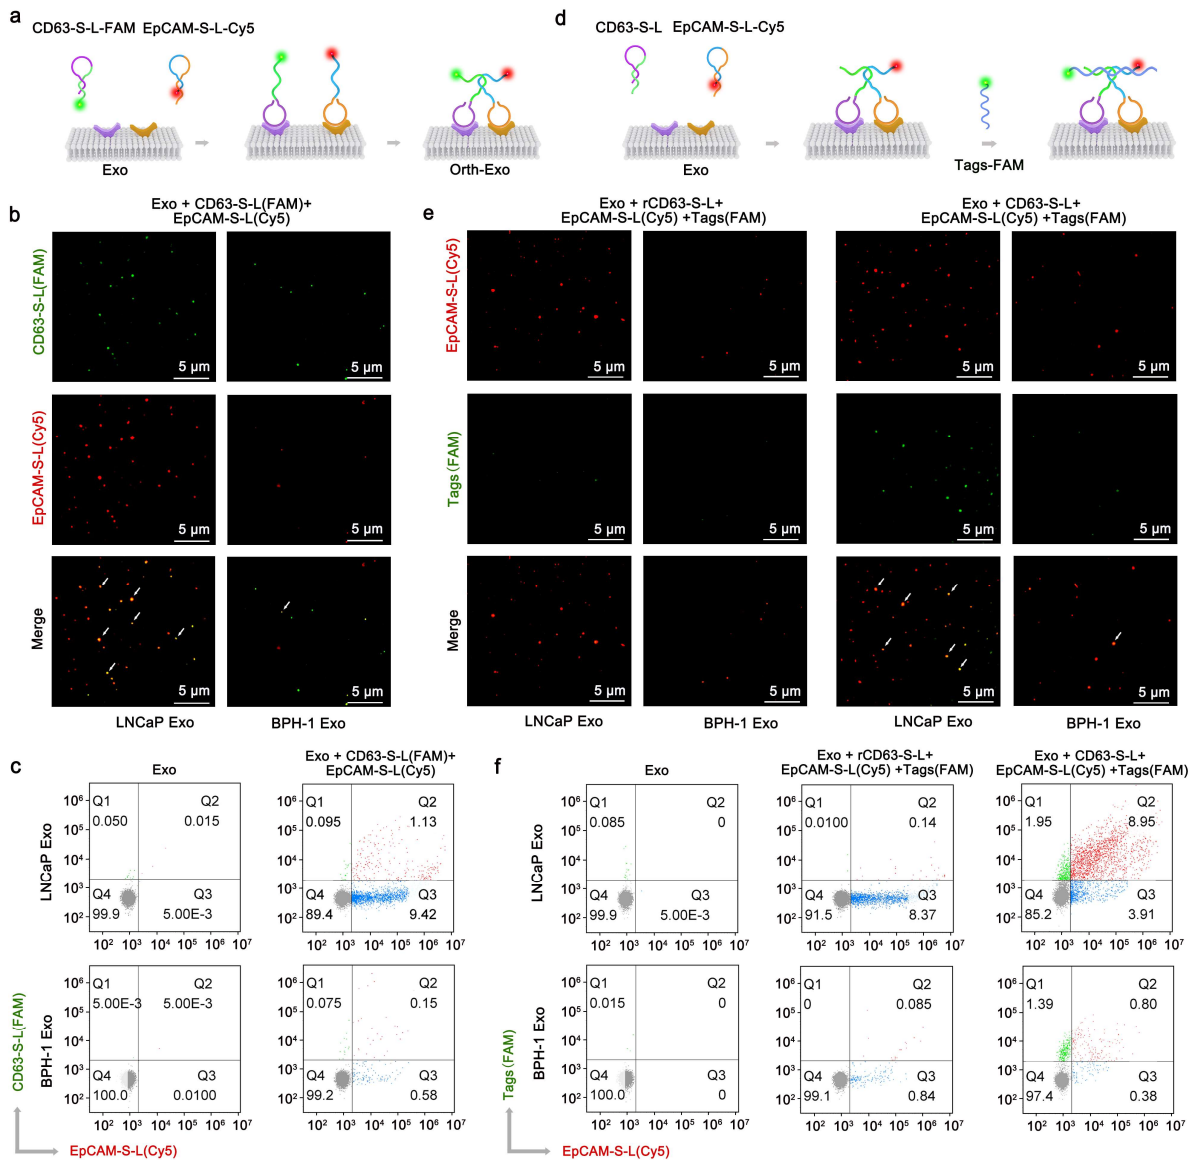

Fig. 2. Validation of dual-surface-protein orthogonal labeling on tumor-derived exosomes. a Schematics of CD63-S-L and EpCAM-S-L-mediated orthogonal labeling on a single exosome surface. **b-c** TIRFM images (**b**) and flow cytometry analysis (**c**) show the membrane proteins of CD63 and EpCAM expressed on LNCaP Exo and BPH-1 Exo. Blank group: Exo; Experimental group: Exo + CD63-S-L (3'-labeled-FAM) + EpCAM-S-L (5'-labeled-Cy5). **d** Schematics of the zipperlike hybridization of the orthogonal barcode-anchored exosome (Orth-Exo) and complementary DNA tags (Tags). **e-f** TIRFM images (**e**) and flow cytometry analysis (**f**) of the zipperlike hybridization of the orthogonal barcode and Tags against LNCaP Exo and BPH-1 Exo. Blank group: Exo; Control group: Exo + rCD63-S-L (only the aptamer domain is replaced by a random sequence) + EpCAM-S-L (5'-labeled-Cy5) + Tags (5'-labeled-FAM); Experimental group: Exo + CD63-S-L + EpCAM-S-L (5'-labeled-Cy5) + Tags (5'-labeled-FAM).

In order to validate the zipperlike hybridization of the orthogonal barcode-anchored exosome (Orth-Exo) and complementary DNA tags (Tags), we detected the CD63-S-L, EpCAM-S-L (5'-labeled-Cy5), and Tags (5'-labeled-FAM) co-labeled on LNCaP Exo and BPH-1 Exo and analyzed them by TIRFM. Fig. 2d

227   illustrated the zipperlike hybridization of the orthogonal barcode and Tags on a single exosome surface. As

228   shown in Fig. 2e, the colocation of EpCAM-S-L (red dot) and Tags (green dot) on the same vesicle was

229   evident in a part of the LNCaP Exo (orange dot in merged images) as compared to BPH-1 Exo. Additionally,

230   no colocation fluorescent signals were observed when CD63-S-L was substituted with rCD63-S-L (only the

231   CD63 aptamer domain is replaced by a random sequence). We further checked the labeling efficiencies of

232   CD63-S-L, EpCAM-S-L (Cy5), and Tags (FAM) on LNCaP Exo and BPH-1 Exo by flow cytometry (Fig.

233   2f). Tags (FAM) have a substantially higher labeling efficiency on LNCaP Exo (8.95%) than BPH-1 Exo

234   (0.80%). When CD63-S-L was replaced with rCD63-S-L, no apparent labeling signals were detected in both

235   LNCaP Exo (0.14%) or BPH-1 Exo (0.09%). These studies revealed the successful formation of orthogonal

236   barcodes on a single tumor-derived exosome surface and the effective zipperlike hybridization of DNA Tags

237   and orthogonal barcodes on the same vesicle surface. Meanwhile, as shown in Supplementary Fig. S4a-b,

238   we further measured the labeling intensities on LNCaP Exo with the following fluorescence sequences:

239   CD63-S-L (3'-labeled-FAM), EpCAM-S-L (5'-labeled-FAM), Tags (5', 3'-labeled-FAM), and rCD63-S-L

240   (3'-labeled-FAM). Flow cytometry analysis demonstrated that the formed orthogonal barcodes improved the

241   binding affinities of allosteric aptamer probes and the zipperlike hybridization of Tags and orthogonal

242   barcodes could occur on tumor-derived exosomes surface. In addition, the structural stability of orthogonal

243   barcodes on a single exosome surface was estimated using the melting temperatures (Supplementary Fig.

244   S4c). The results demonstrated that the orthogonal barcode has excellent structural stability on the vesicle

245   surface, allowing for the effective zipperlike hybridization of DNA Tags and orthogonal barcode.
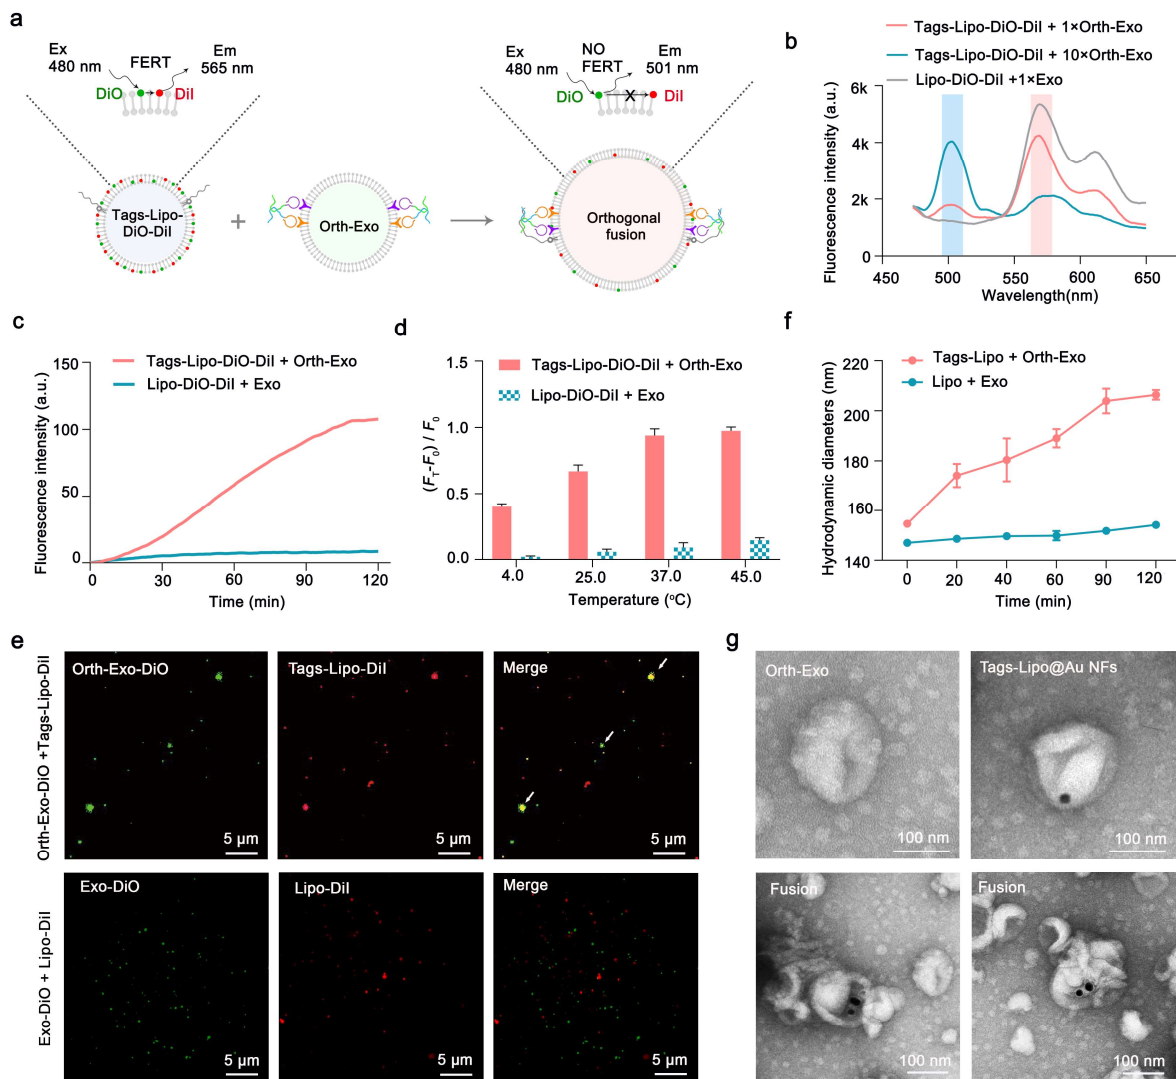

246   **Dynamic monitoring of dual-surface-protein-guided liposome probe fusion**.

247   The hybridization reaction between DNA tags on liposomes and orthogonal barcodes on tumor-derived

248   exosomes guided the targeted fusion of liposomes and exosomes. The morphology and size of liposomes

249   and LNCaP Exo were first characterized by nanoparticle tracking analysis (NTA) and transmission electron

250   microscopy (TEM). The liposomes and exosomes were typical sphere- or cup-shaped vesicles and had a

251   diameter of about 143 nm and 169 nm, respectively (Supplementary Fig. S5a-b). To confirm dual-surface-

252   protein-guided liposome probe fusion, we monitored fusion-based membrane mixing using a FRET-based

253   assay (Fig. 3a). DNA tags-anchored liposomes (Tags-Lipo) were double-labeled with the donor of 3,3'-

254   dioctadecyloxacarbocyanine perchlorate (DiO, 501 nm) and the acceptor of 1,1'-dioctadecyl-3,3,3',3'

255   tetramethylindocarbocyanine perchlorate (DiI, 565 nm). After fusion, the membrane was enlarged, leading

256   to decreased FRET efficiency between the DiO and DiI on the membrane surface. As presented in Fig. 3b,

257   the FRET efficiency declined as the molar ratio of Tags-Lipo-DiO-DiI to orthogonal barcode-anchored

258   exosomes (Orth-Exo) further increased. However, nearly no fusion was seen in the stochastic fusion between

259   Lipo-DiO-DiI and exosome with no barcodes (Exo). The membrane fusion dynamic was also monitored in

260   the FRET assay. When non-fluorescent Orth-Exo was incubated with double-labeled Tags-Lipo (Tags-Lipo-

261   DiI-DiO), the DiO signals increased quickly and reached a plateau value in 2 h (Fig. 3c), while no change

262   was seen in the stochastic fusion of Lipo-DiO-DiI and Exo. These results confirmed that the successful

263   fusion is indeed mediated by the zipperlike hybridization between Orth-Exo and Tags-Lipo-DiI-DiO.

264   Furthermore, the fusion mixing analyses of Tags-Lipo-DiO-DiI and Orth-Exo at different temperatures were

265   recorded in Fig. 3d. With the increase in temperature, the stochastic fusion of Lipo-DiO-DiI and Exo also

266   enhanced. Consequently, 37 °C was the optimum temperature for the SORTER assay holding maximized

267   target to stochastic fusion efficiency ratio.

268   To further validate the effective fusion of Tags-Lipo and Orth-Exo, we labeled the Tags-Lipo and Orth-

269   Exo with DiI and DiO, respectively (Fig. 3e). The DiI fluorescence of Tags-Lipo (red dot) colocalized well

270   with that of DiO in Orth-Exo (green dot). In contrast, almost no detectable colocalized fluorescence signals

271   were observed in the stochastic fusion between Lipo-DiI and Exo-DiO. Notably, we observed multiple Orth-

272   Exo (green dot) around large overlapping particles (yellow dot), indicating that the orthogonal fusion of

273   Orth-Exo and Tags-Lipo-DiI-Dio are DNA-programmed cascade reactions. The hydrodynamic size

274   distribution of the membrane fusion product was determined by the dynamic light scattering method (DLS)

275   at different time intervals (Fig. 3f). The diameter of the fused vesicles gradually increased from 154.7 to

276   206.5 nm, while the diameter barely enhanced owing to the lack of the zipperlike hybridization of Tags and

277   orthogonal barcode in control experiments. TEM analysis of these vesicles (Fig. 3g) revealed the individual

278   liposome or exosomes, which is consistent with incomplete fusion. However, the hemifusion intermediate

279   or fully fused state was observed in the Tags-Lipo@Au NFs and Orth-Exo fusion reaction. These results

280   demonstrate the effective dual-surface-protein-mediated orthogonal fusion of Orth-Exo and Tags-Lipo,

281   allowing for the importation of the encapsulated miRNA detection probes for downstream analysis.

**SORTER for tumor-derived exosomal miRNA analysis**.

Prostate cancer (PCa) is one of the most prevalent diagnosed malignancies affecting men worldwide, with increasing cancer-related mortality [43-45]. Currently, the widely used serum prostate-specific antigen

298 (PSA) screening lacks sufficient specificity and sensitivity for clinical diagnosis of PCa. Patients with benign

299 prostatic hyperplasia (BPH) frequently have elevated PSA levels, leading to needless prostate biopsy and

300 overtreatment [46, 47]. Therefore, it is urgent to develop a liquid biopsy assay to facilitate the early diagnosis of

301 PCa, which is crucial to improve long-term clinical outcomes. miRNAs inside tumor-derived exosomes,

302 closely associated with PCa development, invasion, and metastasis[48, 49], are potential liquid biopsy

303 biomarkers for PCa diagnosis. Here we developed the sensitive and robust one-pot SORTER assay to enable

304 multiparametric miRNA profiling of tumor-derived exosomes in PCa plasma samples. Several putative PCa-

305 associated miRNAs were thus selected to be detected in tumor-derived exosomes, including miR-21, miR-

306 222, miR-1290, miR-221, miR-10b, and miR-182. The SORTER incorporates multiple processes (Fig. 4a),

307 including exosome recognition, probe importation, fluorescent signal transduction, and amplification. To

308 evaluate the assay performance of SORTER, we selected miR-21 as a model to optimize the experimental

309 conditions. The optimum temperature for DSN activity was 37 °C, and the optimum amount of DSN enzyme

310 was 1 U in a 300 μL reaction volume (Supplementary Fig. S6a-b). Furthermore, the sensitivity of the

311 SORTER system was verified by incubating bare Au NFs with the synthesized miR-21. The detection limit

312 of target miRNA is about 160 fM (Supplementary Fig. S7a-b), which performs similarly to the RT-PCR

313 approach.

314   Under optimized assay conditions, we further evaluate the SORTER assay for tumor-derived exosomal

315 miR-21 analysis. As shown in Fig. 4b, the fluorescent signal of LNCaP Exo increased significantly after

316 incubation with Tags-Lipo@Au NFs ($P < 0.001$). In contrast, almost no signal change was observed in BPH-

317 1 Exo after incubation with Tags-Lipo@Au NFs, or in BPH-1 Exo and LNCaP Exo after incubation with

318 Lipo@Au NFs. Furthermore, flow cytometry and TIRFM results (Fig. 4c-d) further showed that tumor

319 LNCaP Exo had significantly higher fluorescence than BPH-1 Exo. These results indicated an elevated level

320 of miR-21 in the tumor exosomes. The sensitivity of the SORTER approach was determined by probing the

321 miR-21 in purified LNCaP Exo spiked in both PBS and healthy plasma (Fig. 4e). Analysis of spiked plasma

322 demonstrated comparable analytical merits to those of spiked PBS, such as calibration sensitivity (that is,

323 the slope: 1.416 versus 1.412) and LOD (44.42 pg mL^{-1} versus 29.66 pg mL^{-1}). We next characterized the

324 performance of SORTER by measuring the expression levels of six miRNAs in tumor-derived exosomes,

325 including miR-21, miR-222, miR-1290, miR-221, miR-10b, and miR-182, in three PCa cells (PC-3, LNCaP,

326 and DU145) and one benign prostatic hyperplasia cell (BPH-1)-derived exosomes. As shown in Fig. 4f,

327 experimental results showed that the expressions of these miRNAs in tumor-derived exosomes are

328 significantly higher than in normal BPH-1 Exo (Fig. 4d). Such high sensitivity allowed us to detect a low

329 level of exosomal miR-21 directly in PCa patient plasma, as verified by the measurements of a PBS blank

330 and a control plasma (P<0.001; Fig. 4g). Additionally, all six miRNAs have significantly greater expression

331 levels in PCa compared to BPH control plasma samples (Supplementary Fig. S8).

SORTER for tumor-derived exosomal miRNA analysis. a Schematic illustration of the SORTER approach for tumor-derived exosomal miRNA analysis. **b-d** Fluorescence intensity (**b**), flow cytometry (**c**), TIRFM (**d**) analysis of miR-21 expression in orthogonal barcode-based BPH-1 Exo or LNCaP Exo (11.37 ng mL^{-1}) after incubation with Tags-Lipo@Au NFs and Lipo@Au NFs, respectively. The *P*-value was determined by a two-sided, parametric *t*-test. The data represents mean ± s.d (*n* = 3). **e** Calibration curves for quantifying LNCaP-derived exosomal miR-21 spiked in PBS and EV-depleted plasma (diluted by 100-folds in 1×PBS). Data represents mean ± s.d (*n* = 3). **f** The Radar plot shows six miRNA markers from the four cell

14

lines-derived exosomes (11.37 ng mL^{-1}), including three PCa cells (PC-3, LNCaP, and DU145) and one benign prostatic

340 hyperplasia cell (BPH-1). **g** SORTER approach for miR-21 analysis in the fused vesicles after incubating with Tags-Lipo@Au

341 NFs and Lipo@Au NFs in healthy and cancer plasma samples. The *P*-value was determined by a two-sided, parametric *t*-test.

342 The data represents mean ± s.d (*n* = 3).

343 **Clinical evaluation of SORTER for tumor-derived exosomal miRNA profiling**.
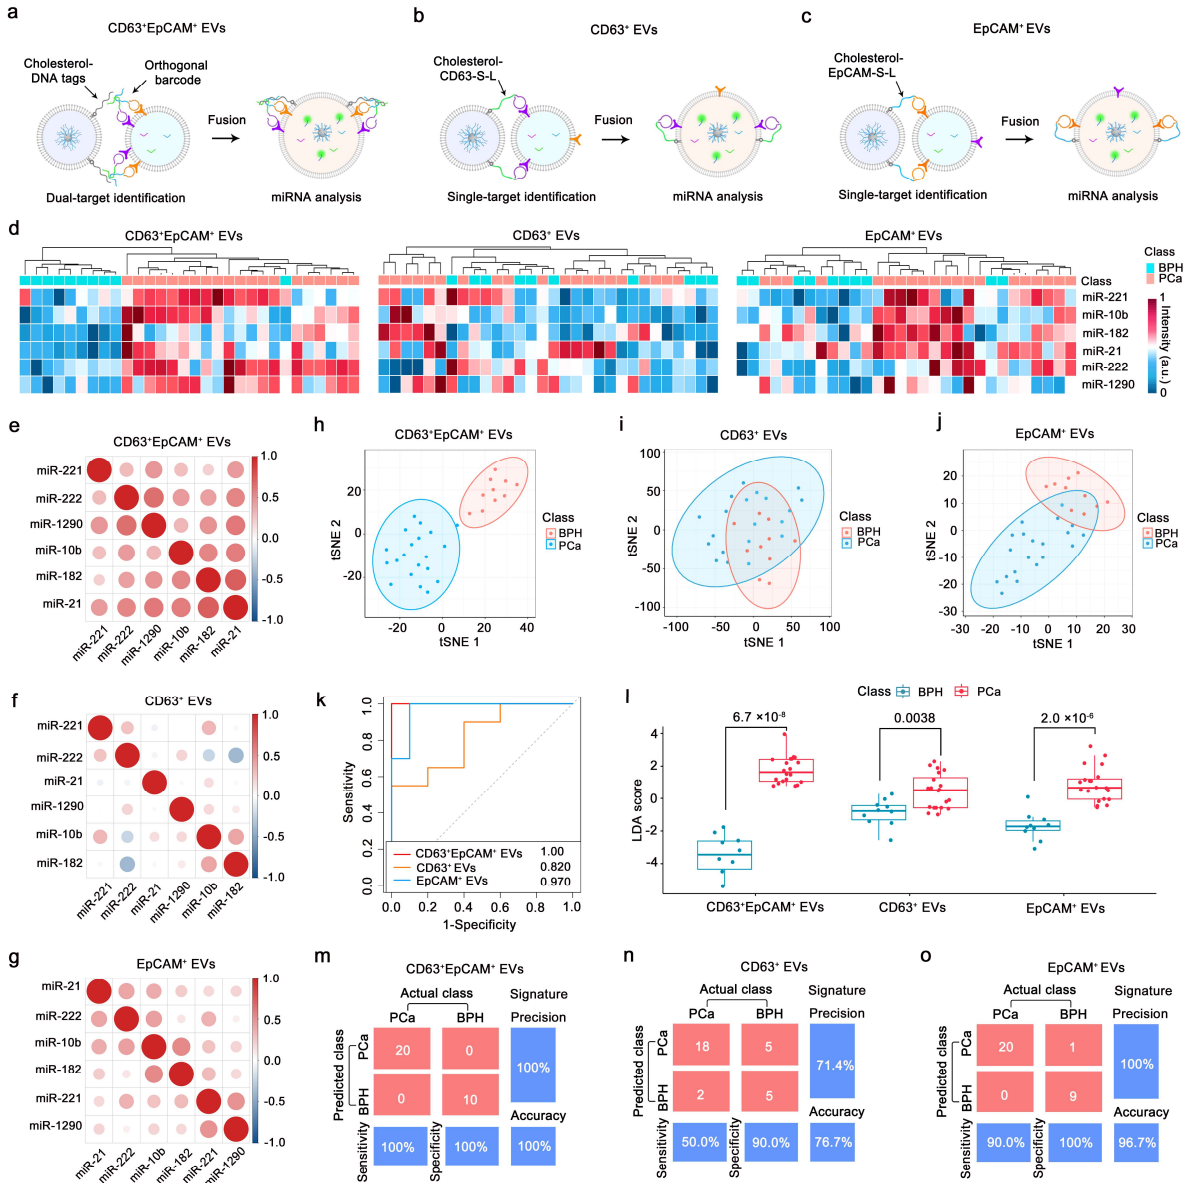

344

345 **Fig. 5. Clinical evaluation of SORTER for tumor-derived exosomal miRNA profiling**. **a-c** Schematic illustration of the

346 miRNA analysis in the CD63$^+$ (**a**), EpCAM$^+$ (**b**), and CD63$^+$EpCAM$^+$ (**c**) EVs subpopulations. The identification of the CD63$^+$

347 or EpCAM$^+$ EVs subpopulation was performed by single-target recognition of CD63 or EpCAM protein on a single-particle

348 membrane, and their miRNA analysis was achieved by guided fusion of Lipo@Au NFs and CD63$^+$ or EpCAM$^+$ EVs

349 subpopulation. **d** Heatmap of unsupervised hierarchical clustering (Pearson correlation, average linkage) of six miRNAs

350 expression levels in CD63$^+$, EpCAM$^+$, and CD63$^+$EpCAM$^+$ EVs for distinguishing PCa patients (*n* = 20) from BPH controls

351 (*n* = 10). The signal intensities were averaged over triplicate measurements of each sample and normalized by min-max

352 normalization after the background subtraction. **e-g** Correlation matrix of the expression profiles for the six miRNAs in CD63$^+$

353 (**e**), EpCAM$^+$ (**f**), and CD63$^+$EpCAM$^+$ EVs (**g**). **h-j** t-distributed stochastic neighbor embedding (t-SNE) discriminated between

354 PCa patients and BPH controls using the six markers as the input in CD63$^+$(**h**), EpCAM$^+$(**i**), and CD63$^+$EpCAM$^+$ EVs (**j**). **k**

355 ROC curves for the PCa signature (weighted sum of six markers by LDA) in CD63$^+$, EpCAM$^+$, and CD63$^+$EpCAM$^+$ EVs to

356 differentiate between PCa patients and BPH controls. **l** LDA score of the PCa signature in CD63$^+$, EpCAM$^+$, and

357 CD63$^+$EpCAM$^+$ EVs for distinguishing PCa patients from BPH controls. The LDA score for the binary classification was

358 generated using a linear combination of chosen markers weighted by the respective coefficients. The *P*-value was determined

359 by a nonparametric, two-tailed Mann-Whitney *U* test. **m-o** Confusion matrix of the PCa signature in CD63$^+$(**m**), EpCAM$^+$(**n**),

360 and CD63$^+$EpCAM$^+$ EVs (**o**). All statistical analyses were performed at 95% CIs.

361   To evaluate the clinical application performance of SORTER in the diagnosis of prostate cancer, we

362 collected plasma samples from 30 patients (Supplementary Table S2) involving PCa (*n* = 20) and age-

363 matched BPH (*n* = 10). We aimed to address (1) whether SORTER could recognize and analyze tumor-

364 derived exosomes in plasma samples precisely and (2) whether SORTER could improve the diagnostic

365 performance of exosome-based liquid biopsy. Using these samples (0.2 μL for each plasma sample), we

366 performed multiparametric miRNA profiling using SORTER assay (termed CD63$^+$EpCAM$^+$ EVs in Fig 5a).

367 As a comparison, the single-target (CD63 or EpCAM) guided fusion for miRNA profiling of CD63$^+$ or

368 EpCAM$^+$ EVs was also conducted in the clinical cohort (Fig 5b-c).

369   By unsupervised hierarchical clustering analysis, we investigated whether a panel of six miRNAs for

370 each patient exhibited mutually exclusive or similar expression patterns in different EV subpopulations (Fig

371 5d). The expression heatmap showed that the abundance of each miRNA has considerable heterogeneity for

372 differentiating PCa and BPH in different EV subpopulations. The heterogeneous expression profile of

373 miRNAs in the CD63$^+$, EpCAM$^+$, and CD63$^+$EpCAM$^+$ EVs subpopulations was separable into two different

374 unsupervised classes. Six miRNAs (miR-222, miR-1290, miR-182, miR-21, miR-221, and miR-10b) were

375 up-regulated in PCa compared to BPH plasma samples. These comparative analyses revealed the

376 heterogeneity among overlapped EV subpopulations and corroborated the validity of the analytical data

377 obtained by SORTER. Subsequently, pairwise comparisons of six miRNAs in different EV subpopulations

378 were shown in Fig 5e-g. Six miRNAs do not correlate strongly with each other in these EV subpopulations,

379 which drives us to the combinations of multiple markers for the accurate diagnosis of PCa. To explore the

380 capacity of our method for PCa diagnosis, t-distributed stochastic neighbor embedding (t-SNE) is applied to

381 discriminate between PCa and BPH (5h-j). Compared with CD63$^+$ and EpCAM$^+$ EVs, CD63$^+$EpCAM$^+$ EVs

382 show a smaller overlap between the two patient groups. To further improve the diagnostic performance of

exosome-based liquid biopsy in differentiating PCa and BPH groups, we harnessed linear discriminant analysis (LDA) to compile all miRNA profiles. Using receiver operating characteristic (ROC) analyses, we determined sensitivity, specificity, and accuracy for each marker individually (Supplementary Fig. S9 and Supplementary Table S3) and also in PCa signature (weighted sum of six markers by LDA, Fig. 5k). We observed that no single marker achieved sufficiently high sensitivity and specificity. Notably, the multiparametric combination improved the performance of molecular phenotyping of exosomes for cancer diagnosis. The PCa signature in CD63$^+$EpCAM$^+$ EVs showed the best diagnostic performance with 100.0% [95% CI: 100-100%] area under the curve (AUC) compared with CD63$^+$ EVs [with 0.820 AUC (95% CI: 0.664-0.976)], and EpCAM$^+$ EVs [with 0.970 AUC (95% CI: 0.889-1.00)]. Furthermore, the assessment of our method for each marker individually and PCa signature in differentiating the BPH controls and PCa patients were shown in Fig. 5l and Supplementary Fig. S10). Compared with CD63$^+$ EVs (nonparametric, two-tailed Mann-Whitney *U* test, *P* = 0.0038) and EpCAM$^+$ EVs (*P* = 2.0 ×10^{-6}), the LDA scores of PCa signature in CD63$^+$EpCAM$^+$ EVs (*P* = 6.7 ×10^{-8}) were significantly different between the PCa and BPH groups. The classification results of marker combinations were further presented as confusion matrixes (Fig. 5m-o). The PCa signature in CD63$^+$EpCAM$^+$ EVs shows an extremely high sensitivity of 100%, specificity of 100%, and accuracy of 100% for distinguishing between PCa from BPH compared with CD63$^+$ EVs [with 50.0 sensitivity, 90.0% specificity, and 76.7% accuracy] and EpCAM$^+$ EVs [with 90.0% sensitivity, 100% specificity, and 96.7% accuracy]. These results demonstrated that our SORTER can improve the diagnostic detection performance of exosome-based liquid biopsy.

Clinical diagnosis of prostate cancer on SORTER.

To assess the diagnostic adaptability of the SORTER approach, we collected plasma from 74 patients participating in a clinical cohort (Supplementary Table S2), including non-metastatic PCa (nPCa, *n* = 27), metastatic PCa (mPCa, *n* = 20), and BPH (*n* = 27), of which 4/7 plasma samples were randomly assigned to the training cohort. Based on the SORTER approach to miRNA markers, the training cohort was studied first to generate the discriminant function model, which was then used to classify the patients in the validation cohort.
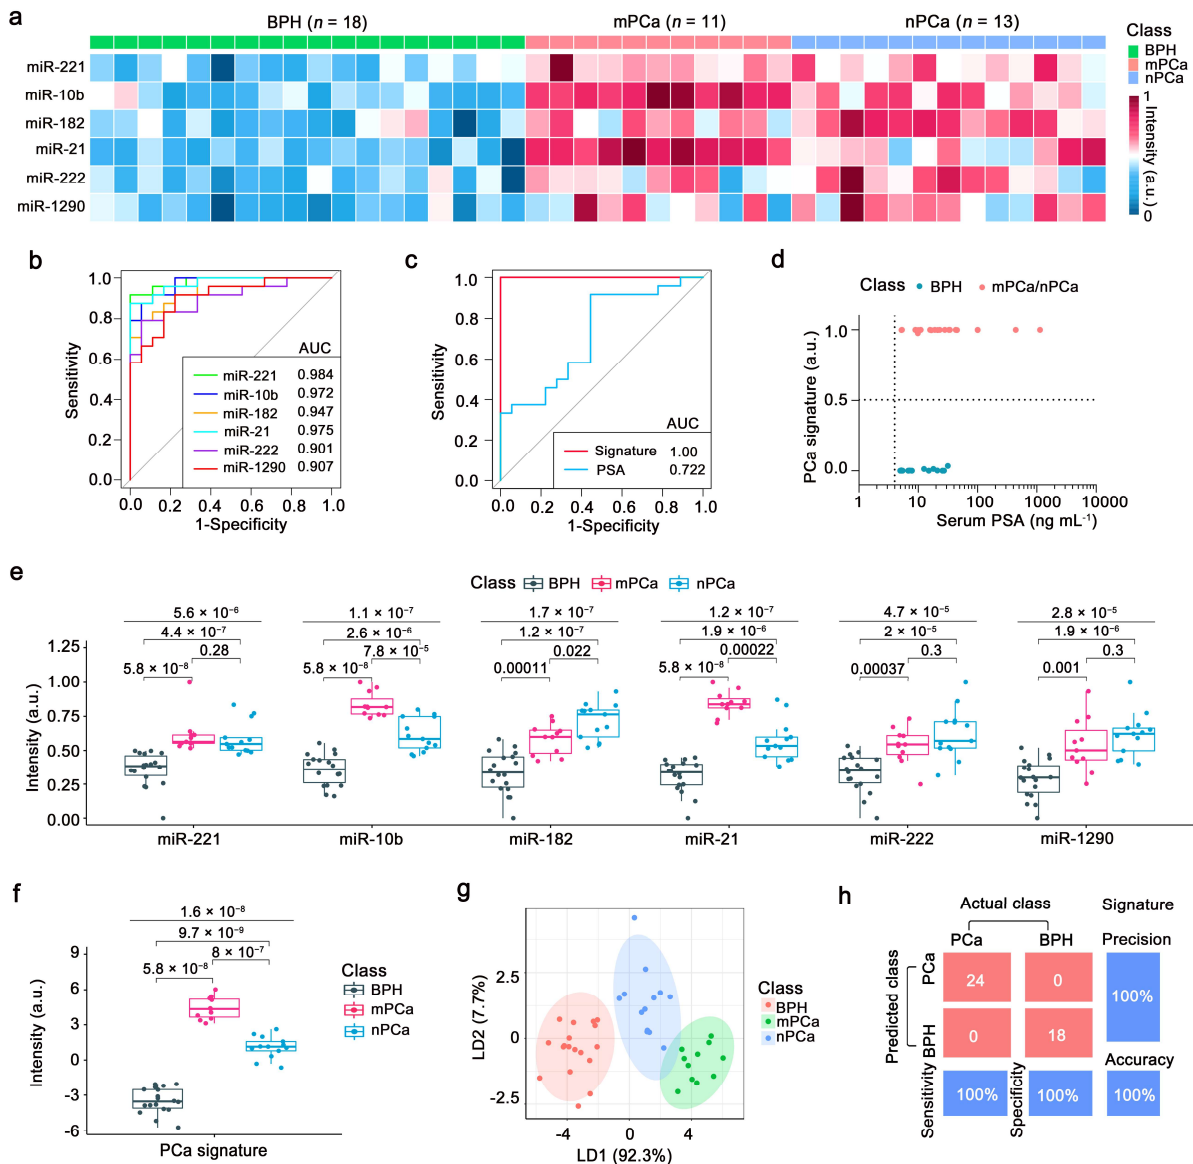

Fig. 6. SORTER for differentiation of nPCa, mPCa, and BPH in a training cohort. **a** Heatmap showing the abundance of the six miRNAs in a training set involving age-matched patients with BPH ($n = 18$), mPCa ($n = 11$), and nPCa ($n = 13$). The signal intensities were averaged over triplicate measurements of each sample and normalized by min-max normalization after the background subtraction. **b, c** ROC curves of the individual markers (**b**) and PCa signature (**c**) for PCa diagnosis. **d** Correlation of the PCa signature with serum PSA to differentiate nPCa/mPCa patients and BPH controls in a training cohort. The dashed line represents the threshold values for positivity (serum PSA, 4 ng mL^{-1}; PCa signature, 0.505). **e, f** Levels of the individual miRNA marker (**e**) and PCa signature (**f**) by SORTER approach at progressing disease stages. The overall and group pair P values were determined using Kruskal-Wallis one-way ANOVA with post hoc Dunn's test for pairwise multiple comparisons. **g** LDA plot using six miRNAs across nPCa, mPCa, and BPH patients. **h** Confusion matrix showed that the PCa signature had an accuracy of 100% across nPCa, mPCa, and BPH patients. All statistical analyses were performed at 95% CIs.

We first analyzed plasma from a training cohort of 13 nPCa, 11 mPCa, and 18 BPH patients. Fig. 6a summarized the abundance of six miRNAs for each subject in a training cohort. Each miRNA expression in

422 CD63$^+$EpCAM$^+$EVs has considerable heterogeneity for differentiating PCa and BPH groups. The diagnostic

423 metrics of individual markers or marker combinations were assessed using ROC curve analyses (Fig. 6b, c,

424 and Supplementary Table S4). For LDA-based ROC studies, the posterior probabilities from this binary

425 classification were employed as the sole test variable. Among six miRNA markers, no single marker achieved

426 sufficiently high sensitivity, specificity, and accuracy. The combination of the six markers comprising the

427 PCa signature [1.00 AUC, 100% sensitivity, 100% specificity, and 100% accuracy] afforded better diagnostic

428 ability than individual markers in the training cohort. We next correlated PCa signature analyses of

429 CD63$^+$EpCAM$^+$ EVs to serum PSA in PCa patients (Fig. 6d). The PCa signature was not correlated with PSA

430 in the training set ($r = 0.2084$; $P = 0.1854$). In the training cohort, 100% of BPH patients (18 of 18) showed

431 an increased concentration of PSA (>4 ng mL^{-1}, the threshold value used in the clinic cohort). In contrast,

432 only 0% of PCa patients (0 of 24) had a low PCa signature value (>0.505, the threshold value was obtained

433 using Youden's index based on the training cohort). Fig. 6e and 6f depict the assessment of our method for

434 detecting the BPH controls and two subgroups of nPCa and mPCa patients. We observed an overall

435 significant increase in PCa signature [Kruskal-Wallis one-way ANOVA analysis, $P = 1.6 \times 10^{-8}$] with

436 progressive disease stages when compared to individual markers. To further characterize the effectiveness

437 of our method to discriminate subgroups, we plotted the scores of each subject for the first two canonical

438 variables computed from the discriminant analysis (Fig. 6g). It was visualized that the training samples were

439 classified into three groups with notable separation among the patient groups at progressing disease stages.

440 The binary classification results of individual markers or marker combinations were further presented in

441 Supplementary Table S4 and Fig. 6h. The PCa signature shows an extremely high sensitivity of 100%,

442 specificity of 100%, and accuracy of 100% for distinguishing between PCa from BPH in the training cohort.

443 More importantly, all nPCa and mPCa cases in the training cohort were correctly detected, achieving an

444 overall accuracy of 100% (95% CI, 100.0 to 100.0%; Supplementary Fig. S11a).
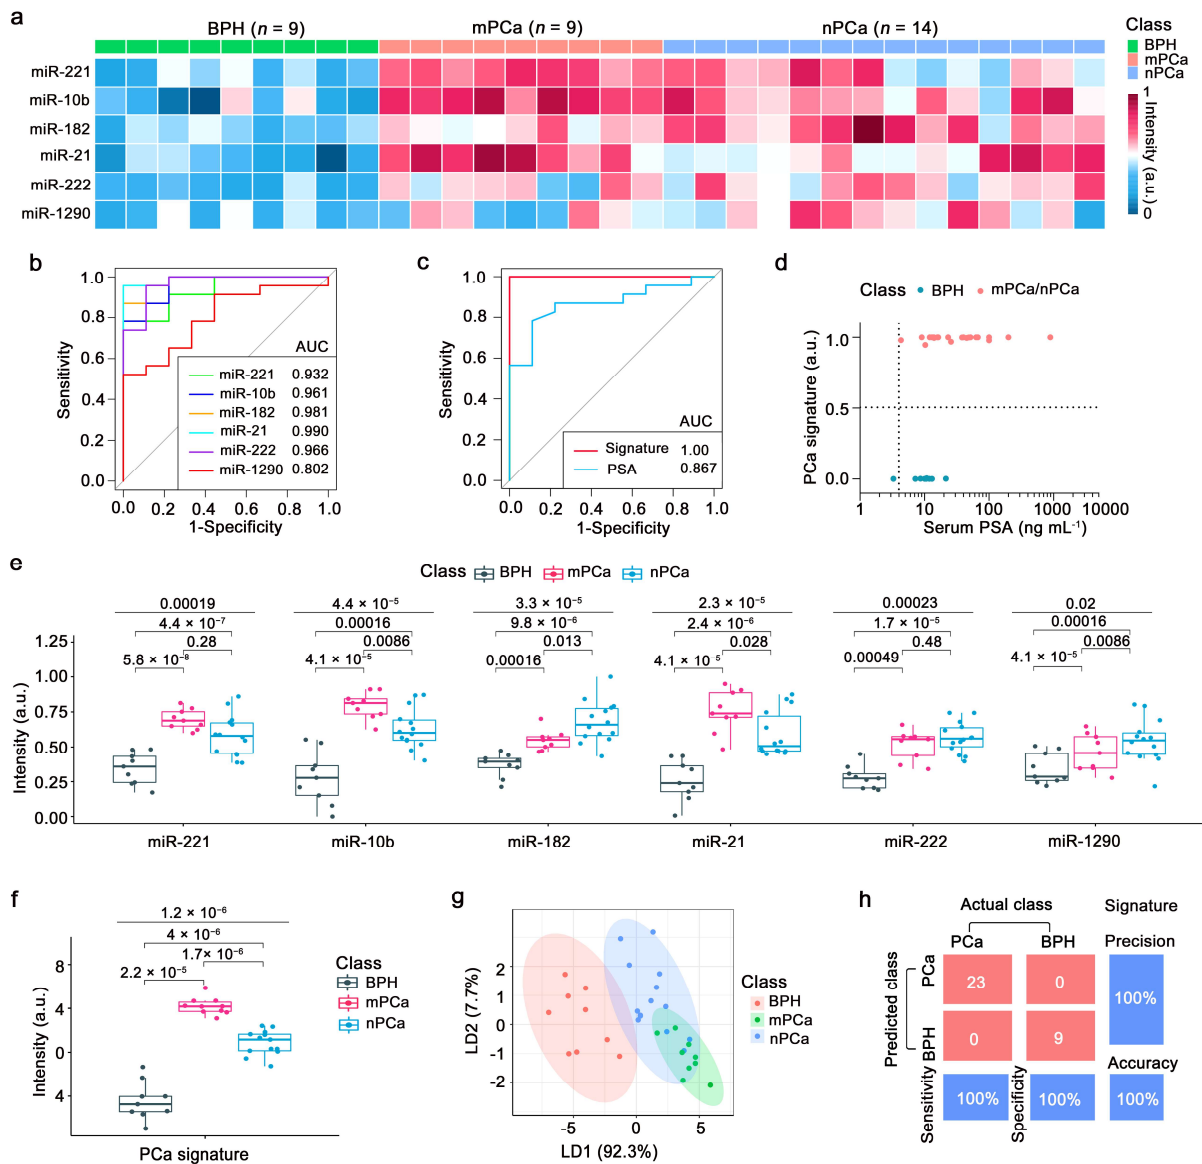

Fig. 7. Validation of the SORTER approach for PCa diagnosis. **a** Heatmap showing the abundance of the indicated miRNAs in a validation set involving age-matched patients with 14 nPCa, 9 mPCa, and 9 BPH. The data processing was similar to the training cohort (Fig. 6a). **b, c** ROC curves for the individual markers or marker combinations to differentiate between PCa patients and BPH controls in a validation cohort. **d** Correlation of the PCa signature with serum PSA to differentiate PCa and BPH. The threshold values were similar to those of the training cohort (Fig. 6d). **e, f** Levels of the individual miRNA marker (**e**), and PCa signature (**f**) by SORTER approach at progressing disease stages. The overall and group pair *P* values were calculated similarly to the training cohort (Fig. 6e, f). **g** LDA plot of the first two canonical variables derived from the discriminant analysis of the training cohort. **h** Confusion matrix showed that the PCa signature had an overall accuracy of 90.6% across nPCa, mPCa, and BPH patients. All statistical analyses were performed at 95% CIs.

The SORTER approach was further applied to an independent validation set of 32 age-matched plasma samples collected from 9 BPH controls, 14 nPCa, and 9 mPCa patients. Fig. 7a summarizes the performance of the indicated miRNAs for each patient. Analyzing the heatmap of each marker expression in

458   CD63$^+$EpCAM$^+$EVs once again showed a considerable heterogeneity for differentiating PCa and BPH. The

459   validation set data was then input into the trained LDA model to test its validity in cancer diagnosis. Across

460   the validation cohorts (Fig. 7b, c), the PCa signature [1.00 AUC, 100% sensitivity, 100% specificity, and

461   100% accuracy] once again showed excellent diagnostic performance for cancer diagnosis when compared

462   with a single marker. We also studied the correlation between PCa signature analyses and serum PSA in

463   patients with PCa and BPH (Fig. 7d). The PCa signature ($r = 0.2018$; $P = 0.2681$) was not correlated with

464   PSA. In the validation cohort, 88.9% of BPH patients (8 of 9) showed an increased concentration of PSA

465   (>4 ng mL^{-1}), whereas only 0% of PCa patients (0 of 13) had a low PCa signature value (>0.505). The

466   validation cohort data were then examined for identification of the PCa progressive stages using various

467   statistical methods. With the Kruskal-Wallis one-way ANOVA and post hoc Dunn's multiple comparisons

468   test (Fig. 7e, f), it was shown that the PCa signature ($P = 1.2 \times 10^{-6}$) significantly improved at discriminating

469   the three subject groups when compared to individual markers. An LDA plot using the feature set comprised

470   of a combination of six miRNA markers shows a small overlap across nPCa, mPCa, and BPH patients (Fig.

471   7g). As shown in Fig. 7h, the PCa signature was able to discriminate PCa from BPH with a sensitivity,

472   specificity and accuracy of 100% in the validation cohort. In addition, only two mPCa and one nPCa case

473   were misclassified, leading to an overall accuracy of 90.6% (95% CI, 75.0 to 98.0%; Supplementary Fig.

474   S11b). Collectively, these comparative results further showed that our SORTER approach had potential

475   adaptability for molecular phenotyping and improved diagnostic performance for early-stage cancer.

Discussion

477   Exosomes carry a specific subset of molecular payloads (e.g., RNA, DNA, protein, and lipids) inherited

478   from the parent cells and function as essential mediators in short- and long-distance intercellular

479   communication.[50, 51] Accumulated evidence has recently shown that the abnormal expression of miRNAs in

480   tumor-associated exosomes is highly associated with cancer development, invasion, and metastasis.[52, 53]

481   Therefore, miRNAs in tumor-associated exosomes are gaining popularity as a source of non-invasive

482   biomarkers in interrogating the biology and heterogeneity of malignancies, as well as improving cancer

483   diagnosis and prognosis. However, current technologies for assessing miRNA profiles in tumor-derived

484   exosomes remain challenging due to the clinical background interference[54, 55], highly heterogeneous EV

21

485   subtypes [56, 57], and wide concentration range of different exosomal miRNA[23, 24]. To address these issues, we

486   developed a highly versatile and powerful SORTER technique that enables rapid and precise recognition and

487   simultaneous miRNA profiling of tumor-derived exosomes directly from clinical plasma samples.

488   Regarding subpopulation differentiation, the conventional techniques for tumor-derived exosome

489   identification/isolation are primarily univariate (e.g., single-target recognition)[14, 33, 58], which are achieved

490   by using antibodies, peptides, and aptamers to bind surface protein receptors. However, these techniques

491   may be interfered with by the coexisting components (e.g., microvesicles, apoptotic bodies, normal-derived

492   exosomes, and free molecules) with overlapping features in their composition and thus lack tumor

493   specificity.[32, 59, 60] In this study, we first presented a combinatorial SORTER methodology that incorporates

494   dual-surface-protein synergistic recognition to precisely label tumor-derived exosomes in unextracted

495   plasma samples. Specifically, our approach utilized two allosteric aptamers of exosomal marker CD63 and

496   tumor marker EpCAM to create a unique orthogonal identity barcode on the tumor-derived exosome surface,

497   permitting targeted recognition and controlled fusion of complementary DNA-anchored liposome probes.

498   We first evaluated the recognition specificity of SORTER for tumor LNCaP Exo and normal BPH-1 Exo by

499   flow cytometry and TIRFM measurements (Fig. 2a-c). Our results showed that the CD63 and EpCAM

500   proteins are overexpressed and coexisted on a single tumor exosome surface, indicating that the synergistic

501   recognition of CD63 and EpCAM proteins is a feasible choice for tracing tumor-derived exosomes. We then

502   demonstrated the formed orthogonal barcode-anchored on the tumor-derived exosome surface and the high

503   reliability of the hybridization of DNA Tags and orthogonal barcode-anchored exosomes by flow cytometry

504   and TIRFM results (Fig. 2d-f). Next, we demonstrated the significant dual-surface-protein-mediated

505   orthogonal fusion events by FRET, TIRFM, TEM, and DLS (Fig. 3b-g) measurements. Distinct from the

506   conventional identification/isolation techniques, we utilized the selectivity of SORTER to minimize the

507   interference of non-specific vesicles and free molecules that enable recognize of tumor-derived exosomes in

508   plasma samples rapidly and precisely, avoiding lengthy pre-isolation/purification procedures and minimizing

509   the non-specific interference of contaminated vesicles.

510   For quantitative analysis of exosomal miRNAs, most of the existing techniques (i.e., qRT-PCR, NGS)

511   measure the total miRNA concentration in the biofluids or the ensemble of EV populations, which are prone

512   to the interference of non-specific vesicles and free miRNAs[15, 16, 42], rendering the conclusions drawn less

513 predictive in complex clinical scenarios. Moreover, femtomolar sensitivity is essential for in situ miRNA

514 profiling of exosomes, where the concentrations of miRNAs are deficient (roughly 1 copy/10^6 EVs to 1

515 copy/1 EV)[22-24]. In this study, the SORTER incorporates multiple parallel processes, including exosome

516 recognition, importing probes, miRNA signal transduction, and amplification, allowing for a fast, sensitive,

517 and multiparametric profiling of miRNAs in tumor-derived exosomes directly from clinical plasma samples.

518 We first evaluated the testing capabilities of SORTER for tumor LNCaP- and normal BPH-1 exosomal miR-

519 21 using FL, flow cytometry, and TIRFM measurements (Fig. 4b-e). These results showed an elevated

520 amount of miR-21 in the tumor LNCaP Exo and the sensitivity of SORTER for quantification of miR-21 as

521 low as femtomolar. Next, we evaluated the performance of SORTER by measuring the expression levels of

522 six miRNAs in different cells exosomes and clinical plasma samples (Fig. 4f and 4g). Compared to

523 previously reported techniques, the SORTER affords three significant advantages as follows: First, the

524 SORTER does not involve any exosome lysis and RNA preparation procedures, which markedly simplifies

525 the experimental operation, reduces the processing time, bypasses the dilution of low-abundance miRNAs,

526 and prevents sample loss during exosome lysing and RNA extraction procedures. Second, the technique

527 incorporates dual-surface-protein synergistic recognition to sort and analyze tumor-derived exosomes

528 precisely, a small yet significant subpopulation of extracellular vesicles, improving the diagnostic and

529 prognostic accuracy of exosomal miRNA-based liquid biopsy. Third, this technique requires only small-

530 volume plasma samples (~0.2 μL), a short assay time of ~2 h by skipping lengthy pre-isolation/purification

531 processes, and is high throughput compatible with 96/384 well plate, opening a new way for non-invasive

532 and high-accuracy cancer screening and progress monitoring.

533 Concerning exosomal miRNA profiling for liquid biopsy applications, the SORTER enables the capture

534 of the information of tumor-derived exosome (CD63$^+$EpCAM$^+$ EVs) subpopulation in complex clinical

535 scenarios, which is often missed in other approaches and only accessible via single-exosome miRNA analysis.

536 Although we cannot spatially determine the fusion proportion of each liposome probe to an individual tumor-

537 derived exosome, statistically, the multiparametric miRNA profiling by SORTER still reflects the

538 compositional nature of the studied tumor-derived exosomes. Here, we made a comparative study of single-

539 and dual-surface-protein-mediated orthogonal fusion (SORTER) to direct subpopulation differentiation and

540 miRNA profiling directly from plasma samples in a clinical cohort involving 20 PCa patients and 10 BPH

controls. We first investigated the relationship between clusters of exosome subpopulations by unsupervised hierarchical clustering analysis to corroborate the validity of the analytical data obtained by SORTER (Fig. 5d). Then, the Pearson correlation of individual markers showed weak correlations in these EV subpopulations (Fig. 5e-g). Next, we harnessed LDA methods to compile all miRNA profiles to improve the diagnostic performance of exosome-based liquid biopsy in differentiating PCa and BPH groups (Fig. 5h-o). Our data showed the PCa signature in CD63$^+$EpCAM$^+$ EVs shows an extremely high sensitivity of 100%, specificity of 100%, and accuracy of 100% for distinguishing between PCa from BPH compared with CD63$^+$ EVs [with 50.0 sensitivity, 90.0% specificity, and 76.7% accuracy] and EpCAM$^+$ EVs [with 90.0% sensitivity, 100% specificity, and 96.7% accuracy]. These results demonstrated that our SORTER could recognize and analyze tumor-derived exosomes precisely, thus improving the diagnostic performance of exosome-based liquid biopsy. We also evaluate the diagnostic adaptability of SORTER for PCa diagnosis and stratification in a clinical cohort (n = 74, Fig. 6 and Fig. 7). In comparison to the serum PSA marker [training cohort with 0.722 AUC; validation cohort with 0.867 AUC] or single-EV marker analyses [training cohort with 0.901-0.984 AUC; validation cohort with 0.802-0.990 AUC], our results showed that the PCa signature [training cohort with 1.00 AUC; validation cohort with 1.00 AUC] provided excellent diagnostic performance in differentiating PCa patients and BPH controls. Combining six miRNA markers tested (PCa signature), the SORTER was able to discriminate PCa from BPH with a sensitivity, specificity, and accuracy of 100% in the training and validation cohorts. Additionally, the PCa signature exhibits high overall accuracy in distinguishing BPH controls and two subgroups of nPCa and mPCa patients, with 100% in a training cohort and 90.6% in an independent validation cohort. These comparative results showed that our SORTER approach had potential adaptability for molecular phenotyping and improved diagnostic performance for cancer.

The technology of SORTER exhibited the unique advantages of being rapid, non-invasive, avoiding separation, scalability, and high accuracy in assessing miRNA profiles of tumor-derived exosomes. The SORTER is capable of high-throughput analysis in clinical studies, and the accuracy has been improved by integrating machine learning into data processing. With its robust ability to differentiate tumor-derived exosomes in clinical plasma samples, the SORTER could be readily expanded to measure, beyond miRNAs, other diverse molecules (e.g., internal proteins, lipids, and metabolites). The barcoding capacity of this

569 technology can be readily enhanced by designing new allosteric-aptamer probes, allowing for measuring
570 other EVs of molecular subtypes (e.g., different cell origins). The SORTER will contribute to the
571 advancement of the liquid biopsy field and be a clinically feasible tool for disease screening, classification,
572 and progress monitoring in complex clinical settings.

573 **Methods**

574 **Cells and culture conditions**

575   The human prostate cancer cell lines LNCaP, DU145, and PC-3 were purchased from the China Center
576 for Type Culture Collection (Shanghai, China). The human prostatic hyperplasia cell line BPH-1 was bought
577 from the Yaji Biotechnology Co., Ltd (Shanghai, China). DU145 cell was maintained in an exosome-
578 depleted DMEM medium. LNCaP, PC-3, and BPH-1 cells were maintained in an exosome-depleted
579 RPMI1640 medium. All cell line media were supplemented with 10% vesicle-depleted fetal bovine serum
580 (FBS) and 1% penicillin-streptomycin in a humidified incubator with constant temperature (37 °C) and 5%
581 CO_2. Vesicle-depleted FBS was prepared by centrifuging FBS for 10 h at 100,000 g, then passing the
582 supernatant through a 0.22 μm filter.

583 **Exosome isolation by standard differential ultracentrifugation.**

584   The cell culture media were collected for cell-derived exosome isolation until cells reached 80-90%
585 confluency. The medium was packaged into six ultracentrifuge tubes with a weight difference between every
586 pair of tubes smaller than 0.02 g. First, the collected media were centrifuged at 3000×g for 20 min at 4 °C
587 to remove cells and large debris. Then, the resulting supernatant was centrifuged at 16,500×g for 45 min at
588 4 °C to pellet microvesicles. After that, the supernatant was ultracentrifuged at 100,000g for 2 h to collect
589 exosomes. The resulting pellets were resuspended and washed with filtered PBS, followed by another
590 centrifugation of 100,000 g for 2 h at 4 °C. Finally, the resulting exosomes were resuspended in filtered PBS
591 and stored at -80 °C for further use.

Clinical samples.

Clinical samples of patients with prostate cancer and benign prostatic hyperplasia were obtained from Renji Hospital of Shanghai Jiaotong University School of Medicine. All relevant ethical regulations were complied with. All samples ($n = 74$) were anonymized, and only the age of PSA and pathological diagnosis were recorded. In the clinical cohorts, the prostate cancer patients ($n=47$) had been diagnosed, and the benign prostatic hyperplasia controls ($n=27$) had no history of cancer before sample collection. Relevant information on the human participants in the clinical was presented in Supplementary Table S2.

Before use, the blood samples were centrifuged at 3,000 g for 10 min to obtain cell-free plasma. Then, the human plasma was centrifuged at 4 °C at 10,000g for 20 min to remove large vesicles. The plasma samples were filtered with a 0.45 µm filter into a new EP tube and stored at -80 °C for further use.

Synthesis and characterization of Au nanoflares

Au nanoflares (Au NFs) were obtained in the following manner. Before use, citrate-capped gold nanoparticles (Au NPs, 13 nm ± 2 nm) were prepared according to a literature-reported method[61]. Then, 5'-SH and 3'-FAM-labeled DNA probes (25 µL, 10 µM) were mixed with 100 µL Au NPs solution. The mixture was then placed in a -80 °C freezer for 2 h, followed by thawing at room temperature. Following that, the resultant FAM-DNA-labeled Au NPs solution was centrifuged (13000 rpm, 8 min) to remove the free DNA before being dissolved in PBS buffer (10 mM, pH 7.4) with 5 mM $MgCl_2$. Next, 10 µL BSA (5%) was added to the FAM-DNA-labeled Au NPs solution, which was then shaken at RT for 1 h. Finally, the resultant Au NFs solution was centrifuged (13000 rpm, 8 min) to remove the free molecules and dissolved in Tris-HCl buffer (10 mM, pH 7.4) containing 10 mM $MgCl_2$ for further use. The concentration of Au NFs was determined as 15 nM based on the molar extinction coefficient of 2.7×10^8 M^{-1} cm^{-1} at 520 nm. The loading density of DNA probes on each Au NFs was determined as 75 nM based on the molar extinction coefficient of 2.33×10^5 $M^{-1}cm^{-1}$ at 260 nm.

Synthesis and characterization of liposome probes.

Before use, the liposome solution (25 mg mL^{-1}) from 1,2-Dioleoyl-sn-glycero-3-phosphocholine/1,2-

617 dioleoyl-sn-glycero-3-phosphoethanolamine/Cholesterol (DOPC/DOPE/Chol; 2:1:1, molar ratio) was

618 obtained according to a literature-reported method.[62] Then, 300 μL reaction mixture containing 1 mg mL^{-1}

619 liposome, 0.2×DSN buffer, 1 U DSN, 20 U RNase inhibitor, and 15 nM Au NFs was co-extruded repeatedly

620 20 times through 200 nm polycarbonate porous membranes (Whatman NucleoporeTrack-Etched Membranes)

621 using a mini-extruder (Avanti Polar Lipids). Next, 15 μL Chol-labeled DNA tags (Tags, 10 μM) were

622 incubated with the above liposome solution at RT for 1 h. Finally, the resultant liposome probes (Tags-

623 Lipo@Au NFs) were purified by ultrafiltration to remove the free products and dissolved in Tris-HCl buffer

624 (10 mM, pH 7.4) containing 10 mM MgCl$_2$ for further use.

625 **Dual-surface-protein labeling on tumor-derived exosomes.**

626 For flow cytometry analysis of nine protein expressions of the exosome, we utilized the latex aldehyde

627 beads (Thermo Fisher Scientific, 3 μm) to immobilize human prostate cancer LNCaP and PC-3 cell-, as well

628 as prostatic hyperplasia BPH-1 cell-derived exosomes. First, 20 μg of LNCAP or PC-3, BPH-1 cell-derived

629 exosomes were incubated with 8 μL of latex aldehyde beads for 15 min, followed by adding 1 mL of filtered

630 PBS for another 3 h. Then, the reaction was stopped by adding 20 μL of 1 M glycine and 80 μL of 20 % BSA

631 (w/v) for 30 min. After that, the exosome-coated beads were washed twice by centrifugation (3 min, 6,000

632 rpm) and then resuspended in 60 μL filtered PBS (containing 0.5% BSA). Next, 5 μL of exosome-coated

633 beads were incubated with 0.25 μM FAM-labeled aptamer probes in 100 μL binding buffer (PBS with 0.5

634 mM MgCl$_2$, pH 7.4) for 2 h at 4 °C. After washing 2 times, the fluorescence intensity of exosome-coated

635 beads was detected by flow cytometry.

636 For flow cytometry or TIRFM analysis of CD63-S-L and EpCAM-S-L-mediated orthogonal labeling

637 on a single exosome surface, 5 μL of LNCAP Exo-coated beads (the preparation process was as described

638 above) or 10 μL of 1.14 μg μL^{-1} LNCAP Exo were incubated with 0.25 μM Cy5-labeled EpCAM-S-L and

639 FAM-labeled CD63-S-L probes in 100 μL binding buffer (PBS with 0.5 mM MgCl$_2$, pH 7.4) for 2 h at 4 °C.

640 After washing 2 times, the fluorescence intensity of exosome-coated beads was analyzed by flow cytometry

641 or TIRFM. BPH-1 Exo was used as a negative control.

Zipperlike hybridization of the orthogonal barcode-anchored exosome and complementary DNA tags.

For flow cytometry or TIRFM analysis of zipperlike hybridization on the tumor-derived exosome surface, 5 μL of LNCAP/BPH-1 Exo-coated beads (the preparation process was as described above) or 10 μL of 1.14 μg μL^{-1} LNCAP Exo were incubated with 5 μL of 5 μM Cy5-labeled EpCAM-S-L and FAM-labeled DNA tags (FAM-Tags), and 5 μL of 5 μM non-fluorescent CD63-S-L probes in 100 μL binding buffer (PBS with 0.5 mM MgCl$_2$, pH 7.4) for 2 h at 4 °C. After washing 2 times, the fluorescence intensity of exosome-coated beads was detected by flow cytometry or TIRFM. The hairpin rCD63 probe (rCD63-S-L, only the aptamer domain was replaced by a random sequence) was used as a negative control.

Dual-surface-protein-guided liposome probe fusion studies.

For the lipid-mixing FRET decrease assay, the dynamic process of orthogonal barcode-anchored LNCAP Exo (Orth-Exo) and Tags-Liposome (Tags-Lipo) membrane fusion was investigated using a standard FRET decrease assay. First, 100 μL of 1.0×10^{10} particles mL^{-1} Lipo were incubated with 20 μM DiO and 20 μM DiI for 30 min at 37 °C. After that, the DiI and DiO double-labeled Lipo (Lipo-DiI-DiO) were incubated with 5 μL of 5 μM Tags for 1 h at RT, obtaining the DiI and DiO double-labeled Tags-Lipo (Tags-Lipo-DiI-DiO) products. The free products were removed by ultrafiltration at 13000 g for 20 min 3 times at each step. Finally, 100 μL of 1× or 10×10^{10} particles mL^{-1} Exo, 5 μL of 5 μM CD63-S-L, 5 μL of 5 μM EpCAM-S-L were incubated with 100 μL Tags-Lipo-DiI-DiO for 2 h at 37 °C, and then the mixture was measured using fluorescence spectrometer or using fluorescence kinetic analysis. The stochastic fusion between Exo and Lipo-DiI-DiO was used as a negative control.

For TIRFM studies, 100 μL of 1.0×10^{10} particles mL^{-1} LNCAP Exo was incubated with 20 μM DiO for 30 min at 37 °C. After that, the prepared DiO-labeled Orth-Exo products were dissolved in 100 μL PBS buffer (10 mM, pH 7.4) containing 5 mM MgCl$_2$. Meantime, 100 μL of 1.0×10^{10} particles mL^{-1} Lipo was labeled by DiI using the same method and then incubated with 5 μL of 10 μM Tags for 1 h at RT, obtaining the Tags-Lipo-DiI products. The free products were removed by ultrafiltration at 13000 g for 20 min 3 times at each step. Finally, 100 μL DiO-labeled Orth-Exo, 5 μL of 5 μM CD63-S-L, and 5 μL of 5 μM EpCAM-S-L were incubated with 100 μL DiI-labeled Tags-Lipo for 2 h at 37 °C, and the mixture was imaged using

28

668 the TIRFM. The stochastic fusion of Exo-DiO and Lipo-DiI was used as negative control.

669   For DLS studies, 100 μL of 1.0×10^{10} particles mL^{-1} Lipo was incubated with 5 μL of 5 μM Tags for 1

670 h at RT. Then, the free products were removed by ultrafiltration at 13000 g for 20 min 3 times. After that,

671 the prepared Tags-Lipo products were dissolved in 100 μL PBS buffer (10 mM, pH 7.4) containing 5 mM

672 MgCl$_2$. Finally, 100 μL of 1.0×10^{10} particles mL^{-1} LNCAP Exo, 5 μL of 5 μM CD63-S-L, and 5 μL of 5 μM

673 EpCAM-S-L were incubated with 100 μL Tags-Lipo products, and the mixture was measured at 37 °C under

674 different time intervals. The group of Exo and Lipo was used as negative controls.

675   For TEM imaging, the fusion mixtures of Tags-Lipo@Au NFs and Orth-Exo (the preparation process

676 was as described above) were added onto a 150 mesh formvar copper grid or ITO glass and incubated for 10

677 min. After washing with ultrapure water, the samples were treated with 2.5% glutaraldehyde in PBS for 30

678 min, then rinsed for 15 min to fix the particles. Next, the samples were negatively stained with 2% uranyl

679 acetate for 10 min and rinsed for 10 min with water. Samples were dried and visualized using TEM imaging.

680 Orth-Exo and Tags-Lipo@Au NFs were used as negative controls.

681 **Profiling of tumor-derived exosomal miRNA.**

682   To clarify the SORTER approach for tumor-derived exosomal miRNA analysis, the LNCAP Exo

683 solution was prepared by serial dilutions of the stock solution in 1 mL PBS or 100 folds-diluted EV-depleted

684 plasma. Specifically, 5 μL of 1 μM CD63-S-L, 5 μL of 1 μM EpCAM-S-L, and liposome probes (20 μL,

685 1.0×10^{10} particles mL^{-1}) were incubated with 20 μL of the prepared exosome solution for 2 h at 37 °C. Finally,

686 the mixture was measured using a multi-detection microplate reader. The group of exosomes and liposomes

687 was used as negative controls.

688   To achieve the tumor-derived exosomal miRNA analysis in clinical plasma samples directly, 5 μL of 1

689 μM CD63-S-L, 5 μL of 1 μM EpCAM-S-L, and liposome probes (20 μL, 1.0×10^{10} particles mL^{-1}) were

690 incubated with 20 μL of 100-fold dilution plasma samples for 2 h at 37 °C. Finally, the mixture was measured

691 using a multi-detection microplate reader. The group of exosomes and liposomes was used as negative

692 controls.

693 **Statistical analyses.**

694   Mean, SD, and LOD were calculated with standard formulas. Significance tests were obtained via a

695 two-tailed Student's *t*-test. The intensities of individual miRNA markers detected by the SORTER approach

696 used Min-max normalization. The PCa signature was calculated as the weighted sum of the normalized

697 intensities of six miRNA markers by LDA, respectively. For binary classification, *P* values for pairwise

698 comparisons were performed using a nonparametric, two-tailed Mann-Whitney *U* test. For ternary

699 classification, the overall and group pair *P* values were determined using Kruskal-Wallis one-way ANOVA

700 with post hoc Dunn's test for pairwise multiple comparisons. Hierarchical clustering was performed for the

701 analysis markers using the "pheatmap" package in the R language. ROC analyses were constructed for

702 individual markers or marker combinations to evaluate the AUC, sensitivity and specificity, and accuracy of

703 a cancer diagnosis. The training cohort ($n = 42$) was first analyzed to generate the discriminant function

704 model, which was used to classify the patients in the validation cohort ($n = 32$). The optimal cutoff points

705 were selected using Youden's index based on the training cohort, which was applied to evaluate the validation

706 cohort's sensitivity, specificity, and accuracy. The t-distributed stochastic neighbor embedding (t-SNE) was

707 performed using six markers as the input for binary classification (PCa and BPH). All statistical analyses

708 were performed at 95% ($P < 0.05$) CIs using OriginPro 2018, GraphPad Prism (v.8.0), and R software

709 (version 4.1.2).

710 **Data availability**

711 The source data underlying Fig. 3b, c, d, e, 4b, e, f, g, Fig. 5, Fig. 6, and Fig. 7 were provided as a Source

712 Data file. All other data are available from the authors upon reasonable request.

Acknowledgements

Author contributions

Y.L. and P.Z. conceived the project. Y.L. and X.F performed the experiments. X.F, Y.D. and G.Z. prepared the exosomes. X.F. and W.X. provided clinical samples. Y.L., X.F and J.S analyzed the data and interpreted the results. Y.Z., W.X., P.Z., and C.Y. supervised the project. Y.L., P.Z. and C.Y. wrote the manuscript. All authors joined in the critical discussion and edited the paper.
