Abstract

Atmospheric transport is critical to dispersal of microorganisms between habitats, and this underpins resilience in terrestrial and marine ecosystems globally. A key unresolved question is whether microorganisms assemble to form a taxonomically distinct, geographically variable, and functionally adapted atmospheric microbiota. This question is made more complex by the unique challenges of separating potential contaminants from atmospheric signal, particularly given the ultra-low biomass of air and the long durations of sampling where contamination may occur. Here we adopted a comprehensive data filtering approach to mitigate contamination and characterise inter-continental patterns of microbial taxonomic and functional diversity in air within and above the atmospheric boundary layer and in underlying soils for 596 globally sourced samples. Bacterial and fungal assemblages in air were taxonomically structured and deviated significantly from purely stochastic assembly. Patterns differed with location and reflected climate, underlying surface cover and environmental filtering. Source-tracking indicated a complex recruitment process involving local soils plus globally distributed inputs from drylands and the phyllosphere. Assemblages displayed stress-response and metabolic traits relevant to survival in air, and taxonomic and functional diversity were correlated with macroclimate and atmospheric variables. Our findings highlight complexity in the atmospheric microbiota that is key to understanding regional and global ecosystem connectivity.

Introduction

Microorganisms occupy central roles in terrestrial and marine ecosystems globally [1, 2]. Movement of viable cells and propagules between habitats occurs largely through the troposphere, which is the atmospheric layer closest to Earth [3, 4]. This is critical to recruitment and turnover that drive ecological resilience of these systems [2–5], as well as influencing dispersal of pathogens and invasive taxa [4, 6]. There is also a growing awareness that microorganisms suspended in the atmosphere are potentially capable of *in situ* metabolic and biophysical activities that can influence climatic processes [4, 7]. However, despite the central importance of the atmosphere to these ecological outcomes, assessments of microbial diversity in air at broad geographic scales remain limited [8, 9]. As a result, there is little understanding of how variable the overall microbial composition of the atmosphere may be on a global scale, the extent to which it may be decoupled from underlying local surface communities that are the sources and sinks for atmospheric microorganisms, or the importance of environmental or biotic factors in shaping diversity. The unique role of the atmosphere as a transport medium for microorganisms has also obscured the question of whether it supports a functionally adapted microbiome with the potential for metabolic transformations and cell proliferation [3].

Previous research has been hampered by lack of consensus for community structures of atmospheric microbiota due to the different experimental approaches, lack of ecologically relevant scaling and taxonomic resolution, and the confounding effect of contamination in the ultra-low biomass atmospheric habitat [10–12]. Nonetheless, inferred community structure for air at various locales within the near-ground atmospheric boundary layer where the bulk of surface-atmosphere interactions occur have described bacterial and fungal communities that were correlated with local abiotic variables such as temperature and humidity [13] or land use [9, 14]. Several studies have related variation in communities to different history of sampled air masses and this suggests combined influence of the different sources and

conditions to which microorganisms are exposed during transit [15–18]. Indirect surveys from ground-deposited desert dust [19] or precipitation [20] have yielded valuable insight on long-range dispersal across inter-continental scales although they reflect deposition and differ somewhat to direct estimates from air [17]. Sampling in the free troposphere at higher altitudes above the atmospheric boundary layer is challenging and scarce data indicates a more restricted microbial occurrence [21]. Thus, the conventional dogma that atmospheric transport is a neutral process involving ubiquitous distribution of taxa has been challenged by recent theoretical [22, 23] and experimental advances [20, 24, 25]. Adaptive traits have generally been inferred from taxonomy, although laboratory estimates of metabolic activity by atmospheric bacterial isolates [26], and recovery of RNA from air and cloud water [27, 28], indicate that atmospheric microorganisms are potentially active *in situ*. Significant research gaps persist and particularly with regard to discerning biogeographic patterns. This requires standardised sampling across broad ecological scales and with comparative data from surface habitats, and careful attention to decontamination of ultra-low biomass air samples.

Here we report findings testing our hypothesis that atmospheric microbial diversity is distinct from that in underlying surface habitats, is non-randomly assembled, and environmental filtering and diverse recruitment explain observed patterns. We characterised taxonomic and functional diversity in a large globally sourced original dataset ($n = 596$) for air within the atmospheric boundary layer that delineates the majority of physical interactions with the Earth's surface [29] (near-ground air), as well as aircraft sampling of free tropospheric air at higher altitudes above the atmospheric boundary layer (high-altitude air). We combined this with concurrent sampling of underlying surface soils and sediments to allow direct air-surface connectivity comparisons. Importantly we conducted and report extensive decontamination of sequence data in order to provide a confident diversity estimate where the unavoidable sampling and reagent contamination due to the ultra-low biomass

atmospheric system must be carefully mitigated [10, 11]. We provide multiple lines of evidence for a taxonomically distinct, non-randomly assembled, altitudinally, geographically and functionally variable atmospheric microbiota that is influenced by a complex suite of biotic and abiotic drivers.

Methods

Environmental and climate metadata and modelling

Local climate metadata for each sampling location were retrieved from public databases (Supplementary notes on environmental metadata). Back trajectories and environmental conditions that airborne microorganisms were exposed to during their transit towards each sampling location was modelled from National Oceanic and Atmospheric Administration (NOAA) atmospheric transport and dispersion models (Figs S1, S2) [30].

Sample recovery

The sampling campaign retrieved 596 air and soil samples using stringent clean sampling approaches from 18 locations spanning all major climatic regions and continents plus two oceans (Table S1). Bulk phase air was recovered using Coriolis μ high-volume impingement devices (Bertin Instruments) from the atmospheric boundary layer at 1.5m above the surface (near-ground air, $n = 501$) and from the free troposphere at 2,000 m above local surface level using aircraft mounted air samplers (high-altitude air, $n = 11$) (Supplementary information: Supplementary notes on sample recovery, Fig. S3) [29]. Underlying soil was sampled immediately after each air sampling was conducted (soil, $n = 84$). Ship-board sampling was achieved at 25m above the ocean surface to avoid sea-spray contamination. Environmental DNA was recovered from all samples and controls as previously described [25] and included sampling and reagent controls for every location and processing batch (Supplementary information: Supplementary notes on sample recovery).

Gene copy number estimation

Real-time quantitative PCR (qPCR) was employed for the most abundant microbial groups (bacteria and fungi) [31]. Primers targeted the 16S rRNA gene for bacteria [32, 33], and 18S rRNA gene for fungi [34]. Reactions were performed as previously described [35]. A qPCR standard for each target sequence was developed to estimate gene copy number using pooled samples and serial dilutions of the template were used to generate standard curves.

Amplicon sequencing

Sequence libraries were prepared using Illumina MiSeq v3 600 cycle chemistry as per manufacturer's protocol. Template DNA in samples was normalised to 2.5ng/ul prior to two-step PCR amplification for the bacterial 16S rRNA gene V3-V4 hypervariable region ([32, 33], and fungal ITS1 region [36, 37] as previously described [25]. Libraries were first processed with cutadapt v2.7 [38] to remove primer sequences and amplicon sequence variants (ASVs [39]) were generated using dada2 v1.14 [40]. Pseudo-pooling was used in ASV calling to increase sensitivity and detect rare ASVs. Taxonomic classification was conducted in dada2 with SILVA v138 [41] and UNITE v7.2 [42] as references. Overall, the amplicon sequencing generated 19.5 million bacterial reads and 1.7 million fungal reads and these resolved to over 200,000 genuine ASVs. Diversity analysis occurred only after an extensive best-practice decontamination protocol to mitigate putative contamination in sequence libraries that is unavoidable when interrogating ultra-low biomass samples (Supplementary Information: Decontamination of environmental sequence data, Figs S6-S21, table S3) [10, 11, 43]. Briefly, this comprised subtractive filtering steps for ASVs as follows: 1) removal of non-target sequences; 2) Removal of ASVs with suspicious frequency (using the default value of 0.1) and/or prevalence (using a more stringent threshold of 0.5) using decontam [44]; 3) Removal of ASVs encountered in any of the sampling or reagent controls from all samples; 4) A subtractive filtering at genus level of human-associated contaminants

regardless of whether or not they were also encountered in controls. Decontamination outcomes were reported and post-hoc testing for residual contaminants conducted. All sequence data were also screened for potential batch effects, cross-contamination, and spatial and temporal autocorrelation. After the decontamination steps, true samples with > 1,000 reads (16S rRNA $n = 529$, ITS $n = 444$) were used for all subsequent analyses. Sampling curves for all post-filtered air and soil samples achieved near-asymptote for ASV diversity. Detailed description and data reporting for all steps is given in Supplementary information.

Shotgun metagenomics

Libraries were prepared using a low-input preparation protocol where required [45] and using the Nextera XT library kit and sequenced (2×150 bp paired-end) on an Illumina NextSeq 500 (Illumina, USA). Kneaddata (v0.7.4, default settings, <https://github.com/biobakery/kneaddata>) was used to remove low-quality reads and human DNA using the human genome hg37 as reference from raw fastq files, and filtered reads were further processed to identify and remove potential contaminating nearest taxonomic units (NTUs) in a similar manner to that applied to ASVs (Supplementary information: Decontamination of environmental sequence data). After all the decontamination steps, a total of 1.5 billion high-quality paired-end reads were retained across the entire dataset of 120 metagenomes, averaging 12.5 million reads per sample. Taxonomic profiles (phylum and species) of the high-quality reads were generated with Kraken2 [46], and Bracken [47], and FindFungi [47]. Functional potentials of the metagenomes were queried using HUMAnN (v3.0.0.alpha.3) [48], generating a total of 1.86 million unique features, which were subsequently converted to over 10,000 protein families (Pfams) corresponding to genes encoding carbon fixation, cold shock response, nitrogen cycle, oxidative stress, phototrophy, respiration, sporulation, starvation, trace gas metabolism, and UV repair proteins (Table S2).

Statistical treatments and ecological modelling

201 Statistical analysis: General processing of the community data including the calculation of
 202 relative abundance and estimates of alpha diversity were conducted using the R package
 203 phyloseq [49] and visualised using ggplot2 [50]. Comparative statistical analyses were
 204 performed using R: ANOVA, Kruskal-Wallis, Mann-Whitney test, Mantel test,
 205 PERMANOVA, manyglm with negative binomial distribution using mvabund [51] (an
 206 approach that takes into account heterogeneity in mean-variance relationships [52]),
 207 Procrustes analysis using vegan [53], lmPerm (permutation test for ANOVA) ([https://cran.r-](https://cran.r-project.org/web/packages/lmPerm/index.html)
 208 [project.org/web/packages/lmPerm/index.html](https://cran.r-project.org/web/packages/lmPerm/index.html)), dunn.test (Dunn's test for post hoc analysis,
 209 *P*-values were adjusted by the Holm–Bonferroni method) ([https://cran.r-](https://cran.r-project.org/web/packages/dunn.test/index.html)
 210 [project.org/web/packages/dunn.test/index.html](https://cran.r-project.org/web/packages/dunn.test/index.html)), ANCOMBC (ancombc differential
 211 abundance analysis, *P*-values were adjusted by the Holm–Bonferroni method) [54].
 212 Correlations used in compositional analysis of taxonomic data to determine potential residual
 213 contaminants were calculated using FastSpar [55]. Calculation of geographic distances were
 214 performed using R package geosphere [56] function distGeo with WGS84 ellipsoid. Source
 215 tracking was conducted by fast expectation-maximization using FEAST [57] with data from
 216 other studies (processed using dada2 following the same parameters as this study) as
 217 additional sources/sinks [58–64] and NCBI BioProject PRJEB42801. For correlation analysis
 218 between abiotic and biotic variables the Pearson correlation coefficient for multiple pairwise
 219 combinations were calculated using the R package corrplot [65], with *P*-value cut-off of 0.05
 220 corrected for multiple tests using Bonferroni correction. To visualise patterns of community
 221 dissimilarity, two methods were used. Hellinger distances were ordinated with t-distributed
 222 stochastic neighbour embedding (tSNE) using R package Rtsne [66]. Jaccard sample pair-
 223 wise distances were calculated using the R package vegan [53], and tested for locations and
 224 habitat (i.e. soil, near ground air and high elevation air) using PERMANOVA [67]. The
 225 Jaccard matrix was decomposed with Principal Coordinate Analysis (PCoA) to provide a

quantification of the variance accounted by each ordination axis [68]. Network null models were employed to detect non-random structure (nestedness) in the microbial assemblages (Supplementary information: Supplementary notes on the use of Null models, Figs S4, S5). A statistical mechanics approach was employed for network construction [69], with networks defined as bipartite matrices with two layers: location and taxa. Z-scores for nestedness were calculated using the commonly employed NODF metric to indicate the number of standard deviations a given data point lay from the mean [70], and also using Jaccard distance to estimate pair-wise assemblage dissimilarity and test if the average dissimilarity deviated from that expected under random assembly.

Results

An overview of inter-domain diversity from our metagenomic libraries indicated that composition was more variable in air than soil (average Bray-Curtis dissimilarity within air samples = 0.256 vs. within soil samples = 0.038, Mann Whitney $U = 8.7 \times 10^7$, $P = < 2.2 \times 10^{-16}$, Wendt effect size $r = 0.493$) (Fig. 1). Bacteria were the most abundant component of soil and air metagenomes and fungi were the second highest microbial category in near-ground air. Relatively low and patchy contribution was observed for archaea and microbial eukaryotes. We therefore focused further community profiling effort on bacteria and fungi with shotgun metagenomics and targeted amplicon sequencing. Sampling of air microbiota presents unique challenges in terms of potential contamination due to the ultra-low biomass habitat. Extended sampling durations increase the potential for unintentional human atmospheric transmission not well addressed with traditional negative controls used for other ultra-low biomass samples, and rarely considered in atmospheric microbiology. Sequencing of our 596 globally-sourced air and soil samples was therefore combined with an extensive effort to mitigate against the occurrence of putative contaminant taxa and cross-contamination

that have plagued low-biomass microbiological studies using traditional negative controls, but also necessitated the use of human controls and bioinformatic filtering of any potential contamination taxa [10, 11] (Fig. S6).

This comprehensive approach successfully mitigated contamination in our study as per recommended best practice for ultra-low biomass habitats [10, 11]. Effective identification and removal of sampling, laboratory and human derived contaminants was achieved, and this did not adversely impact the observed ecological patterns for our data (Supplementary Information: Decontamination of environmental sequence data). In summary, our close attention to careful field sampling and laboratory workflow resulted in very low read numbers for our field blanks and reagent controls compared to environmental samples (Fig. S7) and distinct overall taxonomic composition between controls and samples (Figs S8, S9). We reported the number and taxonomic composition of reads subtractively filtered at each of the decontamination steps for our sequence data as per recommended best practice (Table S3) [11]. For air samples the comprehensive filtering of the bacterial sequence libraries resulted in removal of 31.25% near-ground and 32.14% high-altitude quality-filtered reads, whereas for fungi 55.42% near-ground and 61.39% high-altitude quality-filtered reads were identified as potential contaminants and removed from downstream analysis. Our data was triangulated with the concurrent soil sampling, where a positive correlation between sample biomass and reads retained post-decontamination was observed (Figs. S10, S11). Biomass-rich temperate and tropical soils typically comprised ~1% bacterial and ~5% fungal reads identified as potential contaminants, whilst for extreme low biomass desert mineral soils the values were higher but nonetheless were within the expected range for ultra-low biomass samples where comparable data have been reported [17, 71, 72]. Rarefaction of post-filtered sequence libraries revealed all were sampled to near-asymptote (Figs. S12, S13).

We then identified taxonomic composition of all removed reads (Fig. S14) to allow appropriate nuancing of our decontamination approach, and then performed a post-hoc analysis of our filtered dataset after decontamination to estimate the effectiveness of the multi-step subtractive filtering process and identify any remaining ASVs that may have represented potential residual contaminants (Fig S15). The analysis revealed a small number of putative residual bacterial contaminants with low abundance, and they largely comprised ASVs affiliating with the genera *Ralstonia* and *Sphingomonas* (Fig. S16). In view of the overall low number of potential residual contaminants, that they affiliated with genera that have known environmental taxa as well as commonly encountered contaminants, and to preserve the clear stepwise decontamination process was applied identically across samples; we chose not to perform further removal of these ASVs. The filtered fungal dataset revealed no potential residual contaminants. We further analysed our data to ensure no significant impact from batch effects (cross contamination from our randomised sample processing order) because this is of particular importance when sampling habitats with highly differing biomass such as air and soil (Fig. S17). We also examined our data for potential signals of temporal or spatial autocorrelation and no significant effects were identified (Fig. S15, Fig. S17). We then plotted visualisations of our data to illustrate ASV removed from each location and habitat type (Fig. S18), and the diversity of filtered ASV in all samples pre- and post-decontamination (Fig. S19, S20). We then established that our comprehensive decontamination protocol did not have a significant impact on the strong ecological patterns by habitat type and location (Fig. S21). This was confirmed with strong and significant correlations for both Procrustes and Mantel tests based on Pearson's product-moment correlation for congruence for bacteria (Procrustes $m^2 = 0.089$, correlation = 0.955, $P = <0.01$ and confirmed by Mantel statistic $r = 0.744$, $P = <0.01$); and fungi (Procrustes $m^2 = 0.083$, correlation = 0.958, $P = <0.01$ and confirmed by Mantel statistic $r = 0.901$, $P = <0.01$).

Bacterial and fungal gene copy number indicated a conserved pattern globally where values were highest per g soil > per m³ near-ground air > per m³ high-altitude air (Kruskal-Wallis $H(2) = 93.019$, $P < 0.05$ and $H(2) = 98.825$, $P < 0.05$ respectively, pairwise comparison with post-hoc Dunn's test (between all comparisons $P < 0.05$) (Fig. 2, Fig. S22). Although soil and air within and above the atmospheric boundary layer are not directly comparable in terms of habitable characteristics, magnitude differences in gene copy number and estimated biomass occurred between soil and air habitats at all but the most extreme Atacama Desert location where soils are microbiologically depauperate (Fig. S22) [73]. Our community composition estimation using amplicon sequencing and shotgun metagenomics were positively correlated (Procrustes: Bacteria $m^2 = 0.76$, correlation = 0.49, $P = 0.001$; Fungi $m^2 = 0.56$, correlation = 0.66, $P = 0.001$) (Fig. S23), and so we focused our fine scale phylogenetic interrogation on amplicon sequence data because this approach allowed better ecological representation of the targeted assemblages in terms of sampling depth and taxonomic resolution [74]. We employed the Jaccard distance matrix to visualise the bacterial and fungal assemblages at sampling locations in three two-dimensional (Fig. 2) and three-dimensional (Fig. S24) clusters. The clusters corresponded to soil, near-ground air and high-altitude air habitats and this dominated community patterns. We triangulated this finding using Hellinger transformed Bray-Curtis distances to visualise bacterial and fungal communities grouped by habitat (soil, near-ground air, high-altitude air) and locations (Fig. S25). The variables habitat (soil, NG air and HA air) and location were significant in structuring the composition of the bacterial and fungal assemblages (manyglm, 5,000 most abundant ASVs, all $P = 0.001$, Table S4), and this analysis accounted for potential heterogeneity in the mean-variance relationship of unevenly sampled data [52]. Significant linear distance decay relationships for diversity were observed for bacterial assemblages (Mantel test, Soil: $r = 0.357$, $P = 0.001$; NG air: $r = 0.353$, $P = 0.001$; HA air: $r = 0.433$, $P =$

0.002) and fungal (Soil: $r = 0.507$, $P = 0.001$; NG air: $r = 0.482$, $P = 0.001$; HA air: $r = 0.535$, $P = 0.004$ (Fig. S26). However, there was no evidence for a latitudinal gradient in richness and this mirrored observations for global soil bacterial diversity [75], and also reflected the inclusion of diverse habitats including deserts, mountains, high latitude and ocean locations in our study.

We then constructed a general null model of the taxa occurrence matrices by habitat and location to validate our hypothesis that microbial diversity in air is non-randomly assembled (Fig. S27). We used the statistical mechanics of networks [69] to formulate correct null models for our data set subject to the constraints of observed taxonomic richness at each location. We calculated two metrics of community structure on the observed matrix and the ensemble of null model matrices: NODF for nestedness [76], and the classical Jaccard index for taxonomic compositional dissimilarity which is a proxy to beta diversity and turnover in taxonomic composition. Bacterial and fungal assemblages in both near-ground and high-altitude air were significantly less nested than null models when compared to the confidence interval of the baseline provided by the models, and therefore identified as taxonomically structured and non-randomly assembled (Fig. 2) [77]. The specific non-random patterns (i.e. significantly less nested than expected under random taxonomic composition) implied taxa specificity to habitat and location, and we interpreted these as indicative of strong filtering for taxa. Bacterial assemblages in soil were more similar than expected under the null model and this reflects observed global diversity patterns for soil bacteria [75]. The highly significant deviations from the null models (Null model overall $P = <0.01$), also at higher altitudes above the atmospheric boundary layer where abiotic stressors are more pronounced, suggested that the communities were selected towards non-random taxonomic compositions. The pattern was corroborated by Jaccard index estimates that showed observed bacterial and fungal assemblages in air were more dissimilar between locations than expected under the null

model (Null model with overall $P = <0.01$) (Figs. S4, S5). Nestedness patterns converged towards the null model for all habitats at broader taxonomic ranks and this pattern has been interpreted as indicative of conserved traits among soil microbial groups, rather than due to diversification and dispersal over short time scales [77]. The pattern persisted between hemispheres sampled at peak and low growing season and across major climatic boundaries and land use types. The non-random distribution of taxa across habitat and locations suggested that some form of ecological selection (*sensu* [78]) was operating on the microbial assemblages. We propose that this was environmental filtering in both near-ground and high-altitude air, combined with dispersal limitation, which most likely operated in terms of local surface emissions to air. We conclude that this resulted in structured and biogeographically predictable patterns for bacteria and fungi (i.e., different environmental matrices such as soil and air, and different locations, display specific, non-random taxonomic compositions).

A detailed analysis of the taxonomic composition of assemblages further confirmed the macroecological patterns quantified with our null model approach. At broad taxonomic ranks (phylum-class) a relatively consistent diversity was observed in air globally regardless of underlying biome or growing season (Fig. 2; Fig. S28). A comparison of Hellinger distances between ASV and Genus defined communities revealed observations to be highly congruent between the classification methods for bacteria ($m^2 = 0.239$, correlation = 0.872, $P = <0.01$) and fungi ($m^2 = 0.187$, correlation = 0.902, $P = <0.01$). Our amplicon sequence variant (ASV) approach to diversity analysis revealed that at finer taxonomic scale (genus-ASV) and after extensive decontamination effort there were 13% of bacterial and 10% of fungal genera co-occurring among $\geq 50\%$ of globally distributed air samples (Tables S5, S6). The only genus with ubiquitous representation in all air samples was *Sphingomonas*, a diverse group linked with emissions from the phyllosphere [14, 79]. Evidence from taxonomic data for environmental filtering of assemblages in air supported the conclusions of

375 our nestedness analysis. Bacteria enriched in near-ground air compared to soil were largely
 376 accounted for by classes encompassing taxa with known tolerance to environmental stress
 377 (Actinobacteria, Firmicutes [Bacilli, Clostridia, Limmnochordia, Negativicutes] and
 378 Gammaproteobacteria) (ANCOM-BC Holm Adjusted $P = < 0.05$; Effect sizes $W = -2.00$;
 379 0.05 ; -7.89 ; -9.59 ; -3.76 ; -5.66 ; -4.09 respectively), although it cannot be ruled out that this
 380 also indicates taxa that possess adaptive traits that favour aerosolization [80]. At higher
 381 altitudes where environmental stress is exacerbated the spore-forming Actinobacteria and
 382 Firmicutes were more abundant (ANCOM-BC Holm Adjusted $P = < 0.05$; Effect sizes $W =$
 383 NG air-HA air -3.35 , NG air-Soil: -2.39 ; NG air-HA air: -4.67 , NG-Soil: -8.96) (Fig. 2; Fig.
 384 S28), suggesting selection towards survival as passive resting stages. Significantly elevated
 385 abundance of gammaproteobacterial taxa at the farm location in South Africa (ANCOM-BC
 386 Holm Adjusted $P = < 0.05$; Effect size $W = < 0$ for all comparisons) was consistent with
 387 emissions of this group from agricultural surfaces [81]. In the absence of observed mycelia in
 388 air samples we concluded that spores accounted for much of the fungal signature in air, and
 389 this is corroborated by the elevated relative abundance of macrofungi (Agaricomycetes) and
 390 prolific spore-formers (Dothidiomycetes) (Fig. 2). The Agaricomycetes were significantly
 391 more abundant in tropical near-ground air than all other locations globally (ANCOMBC
 392 Holm Adjusted $P = < 0.05$, Effect size $W = 12.83$) and this likely reflected global patterns for
 393 terrestrial fungi [82]. In near-ground air the abundance of common fungal agricultural
 394 pathogens (Ustilaginomycetes) was significantly elevated in temperate Northern Hemisphere
 395 locations sampled during peak growing season (ANCOMBC $P = < 0.05$, Holm Adjusted $P =$
 396 < 0.05 ; Effect size $W = 8.66$), as opposed to reduced abundance in Southern Hemisphere
 397 samples collected at the end of the growing season. Based on this observation, we suggest
 398 that seasonality in land use on a global scale is among decisive factors impacting diversity of
 399 atmospheric fungi. Previous studies at individual near-ground locales have concluded that

inter-seasonal variation may variously be absent [35], weak [15], pronounced for some taxa [16] or stochastic [17]. Elevated fungal diversity in ultra-low biomass high-altitude air was indicative of persistent fungal propagules that are tolerant to extreme, prolonged UV and thermal stress. This is consistent with typically extended residence time for airborne cells at high altitudes, and this necessitates effective tolerance to these stressors during potentially long-distance dispersal [83]. Overall, our combined ecological and taxonomic data provided strong evidence that contrary to long-held dogma in microbial ecology that microbial transport in air is ubiquitous and neutral to dispersal outcomes [13, 25, 83], instead the atmospheric microbiota exhibit a pronounced biogeographic distribution.

To further interrogate possible explanations for the observed patterns, we conducted source tracking analysis to assess the likely origin of bacteria and fungi encountered in the air. First, a connectivity analysis revealed that near-ground air displayed greatest taxonomic connectivity with local soil at any given location and less connectivity with soil from different locations (two-way ANOVA with permutation test [5,000 iterations] $P = <2.2 \times 10^{-16}$) (Fig. 3). Assemblages in high-altitude air displayed significantly fewer shared taxa with underlying near-ground air or soil (two-way ANOVA with permutation test [5,000 iterations] $P = <2.2 \times 10^{-16}$). The shapes of the curves demonstrate the number of ASVs shared among all samples in a habitat type, with shared ASVs co-occurring the most in soil>near-ground air>high-altitude air (Fig. S29). Both bacterial and fungal communities in high-altitude air showed much lower overall ASVs than other sample types, and displayed an obvious proximity to their lower asymptotes, suggesting more distinct and less connected communities at higher altitudes. Aerosolization of microorganisms not only occurs from soil but also from different terrestrial and aquatic surfaces, e.g. ocean surface waters [18, 24], the phyllosphere [79, 84] and desert dust events [85, 86]. We therefore employed fast expectation-maximization source tracking (FEAST) [57], to estimate recruitment to air microbiota from the surface habitats of

different climatic regions (Fig. 3; Fig. S30). We matched exact ASV taxa rather than the more general operational taxonomic unit (OTU) approach based on 97-99% sequence similarity that has been previously applied to atmospheric source-tracking, and this resulted in a large volume of taxa with unexplained source but may also reflect that it is impossible to exhaustively sample potential sources. For most locations local soil was the major explained source of bacteria and fungi in air, and bacteria were sourced in a more cosmopolitan manner than fungi (Fig. S30). Many sampled air masses had significant transit over oceans and yet marine sources were a relatively minor contributor to observed diversity in air above terrestrial locations. This reflects that fewer microorganisms occur above the oceans than over land [24], and also the limited number of oceanically sourced sequence libraries for comparison. Clear patterns for terrestrial sources were apparent. Dryland soils (dry deserts, polar/alpine and dry continental locations) were pronounced sources for bacteria globally (Mann-Whitney $U = 73$, $P = 2.937 \times 10^{-5}$; Wendt effect size $r = 0.70$) and this may reflect the more readily aerosolised non-cohesive soils typical of these biomes [86]. This expands the influence of deserts to global-scale atmospheric microbiota beyond the well-defined intercontinental desert dust transit routes for microbial dispersal [85]. For the fungi, polar and alpine soils were major sources and this is congruent with the notion that permanently cold surface substrates in these environments have been proposed to act as long-term reservoirs for inactive fungal propagules [25]. The phyllosphere was a pervasive contributor to bacterial diversity globally, and the relatively minor contribution to fungal sources likely reflects the lack of available comparative data and broad diversity in host surfaces. This may emerge as a more significant source as the inventory of phyllosphere microbiomes increases. For high-altitude air, significant major sources of bacteria were dry deserts and polar/alpine sources (Mann-Whitney $U = 1$, $P = 0.018$, Wendt effect size $r = 0.93$), and this likely reflects in part the adaptive advantages that taxa from these habitats have in air, e.g. UV repair and

desiccation tolerance [86]. The ability to become aerosolised may vary between taxa in marine [80] and terrestrial [87] systems and so deterministic biotic drivers may also be relevant to recruitment from sources, as well as selective deposition during transit [88]. Overall, the source tracking demonstrated that atmospheric diversity is driven by a complex recruitment process involving cell emissions from local soils and transport from more distant sources, and particularly from drylands and the phyllosphere.

To generate further insight into possible biotic drivers of the observed diversity patterns we conducted a functional metagenomic analysis for 120 metagenomes of selected metabolic and stress-response genes relevant to the atmospheric habitat [89, 90] (Fig. 4; Fig. S31). We targeted bacteria because they likely comprise any active fraction of the atmospheric microbiota [27]. Distribution of marker genes in air broadly reflected that for underlying soil at terrestrial locations and this supported our identification of soil as a major source for atmospheric bacteria. Traits were widely distributed globally and those for stress tolerance were notably more abundant in bacterial assemblages in air above dry and polar/alpine regions (Mann Whitney $U = 2.1 \times 10^4$ $P = 0.02$, Wendt effect size $r = 0.12$), thus further supporting our hypothesis that microorganisms from these surface environments are adapted to survival of the stressors encountered in air [91]. Compared to soil, air communities possessed higher abundance of the oxidative stress gene *msrQ* (Mann Whitney $U = 2,061$, $P = 0.02$, Wendt effect size $r = 0.22$), UV-repair gene *phrB* (Mann Whitney $U = 2,114$, $P = 0.01$, Wendt effect size $r = 0.25$), and starvation gene *slp* (Mann Whitney $U = 1916.5$, $P = 0.01$, Wendt effect size $r = 0.24$) (Fig. S31). High abundance for stress-response genes in air above ocean locations may indicate that the low biomass and taxonomic richness above marine surfaces reflects strong environmental filtering. This may arise during long-distance transport from largely terrestrial sources, as well as during recruitment of bacteria from the sea surface micro-layer [92]. Metabolic marker genes for respiration were widespread, and notably for

the *ccoN* proteobacterial cytochrome oxidase that correlated with elevated proteobacteria in air versus soil. Markers for the metabolism and fixation of a variety of gaseous atmospheric substrates including carbon dioxide, hydrogen, methane, nitrogen and isoprene, as well as phototrophy were also abundant in air. Elevated occurrence in air of the *coxL* gene associated with carbon monoxide metabolism was indicative of the potential for interaction with anthropogenic emissions [93]. This limited functional interrogation provided a much-needed glimpse into the potential for an active and stress-adapted atmospheric microbiome. Our data indicates that there is capacity for greater metabolic plasticity than the existing inventory from molecular genetics [28, 87] and transformation of substrates by atmospheric isolates under laboratory conditions currently suggests [94, 95].

We examined possible interactions between the taxonomic and functional diversity of assemblages and abiotic variables relevant to survival in air and soil (Fig. 5). These included both location-specific macroclimate variables, and a novel geospatial analysis approach to capture environmental conditions encountered by microorganisms during transit in air (Fig. S2). Significant correlations were revealed between both local macroclimate and transit abiotic variables and community metrics of taxonomic and functional diversity in air ($P = 0.005$ after Bonferroni correction). Relatively strong negative correlations for bacterial and fungal richness and relative abundance with solar radiation and altitude provided further evidence for UV exposure as a strong selective force on global bacterial and fungal diversity. Functional genes were most strongly correlated with mean annual precipitation, and this likely reflects niche differentiation of source communities in underlying soil at different climatic locations since we have shown they are coupled to diversity in local air. Transit variables were less influential on functional diversity, and this was consistent with our hypothesis that most microorganisms in air are inactive. The correlations between occurrence of phototrophy and carbon fixation genes and several abiotic variables suggested

photoautotrophic bacteria may be subject to greater selective pressure than other groups, but also likely reflects source climate because emissive dryland surfaces are typically dominated by photoautotrophic microbial soil crusts compared with plant cover in temperate and tropical climates [86]. For soil communities the correlations with macroclimate variables were broadly congruent with those observed for other global studies of soil microbial diversity [96], and this provided triangulation for our approach. These data highlight that although variables at a specific location are important, the conditions to which microorganisms are exposed during transit are a significant but previously overlooked factor affecting with taxonomic and functional diversity and are influential to dispersal outcomes.

Discussion

We have demonstrated that standardised sampling and careful attention to decontamination of environmental sequence data from ultra-low biomass atmospheric and soil samples can reveal clear biogeographic patterns. We acknowledge that there is currently no consensus on acceptable levels of contamination and so we highlight the importance of adopting a comprehensive approach that includes fully reporting the outcome of decontamination workflows and performing post-hoc checks for data validity. In so doing we aim to raise awareness of this challenge in studies of low biomass microbial habitats and encourage continued effort to improve best-practices. Overall the findings illustrate that atmospheric microbiota from different continents and climatic zones are non-randomly assembled, display geographic and altitudinal biogeography across large spatial scales, are recruited from a complex combination of local and distant sources, and display functional attributes favourable to survival in the atmosphere.

Based upon these findings, we envisage a global system where for any ecological region highly filtered and taxonomically structured microbial communities assemble across

multiple spatial and temporal scales, which are fundamentally affected by cell survival due to environmental filtering as well as flux from source habitats [4]. Underlying surface habitats serve as key local sources although it is clear from our findings that aerosolization and residence in air exert strong environmental filtering. It is not possible to clearly delineate between these two drivers given current understanding in microbial ecology, but we envisage selective emissions from different microbial habitats are important over short timescales whereas for longer residence times in air environmental filtering becomes more influential. We identified that atmospheric diversity is punctuated by long-distance transport of taxa primarily sourced from drylands and from the phyllosphere. Drylands support microorganisms that can be regarded as pre-adapted to atmospheric survival in view of the similar environmental stressors, namely xeric and osmotic stress and photo-oxidative stress [97]. The phyllosphere is a major source of microorganisms [84], and a bioprecipitation feedback has been proposed that links atmospheric and phyllosphere microbiota via their involvement in ice nucleation that influences precipitation and vegetation patterns [98]. Our data suggests the influence of this feedback may extend across a broad geographic range. Future research that integrates spatial and temporal scales will yield further insight on atmospheric microbial biogeography.

Our findings also point towards an atmospheric microbiota that is enriched in stress adaptation and metabolic traits that may potentially allow microbial metabolic activity in the atmosphere. This has important implications for consideration of the atmosphere as a true microbial habitat as opposed to a transit medium, and several laboratory studies have demonstrated primary metabolism by atmospheric isolates, e.g. [95, 99], as well as evidence for potential metabolic activity in clouds, e.g. [100, 101]. It is important to recognise that opportunity for metabolic transformations by bacteria or fungi in air are likely to be very limited due to short residence times in air and highly heterogeneous conditions. Whether

sufficient moisture, temperature, substrate availability and stress avoidance for cell homeostasis and reproduction are energetically feasible, or only quasi-dormancy within the short timeframe of favourable conditions offered during atmospheric transport remains unexplored.

Given the physicochemical and dynamic complexity of the atmosphere and the broad range of correlations we observed between taxonomic and functional diversity and abiotic factors, a chaotic system of interplay may emerge that influences atmospheric microbial ecology as envisaged for highly dispersed marine larvae [102]. Taken together we anticipate these findings will be valuable in future hypothesis-driven research both to identify interactions between surface habitats across multiple ecological scales which are mediated by the atmospheric microbiota, and to test models of recruitment, turnover, functionality, and resilience. Given that the atmosphere is also a sink for a large fraction of anthropogenic emissions [93], it is timely that an accurate global inventory of microbial diversity is provided in order to present a baseline for measuring future responses to change. Finally, the study complements efforts to inventory global soil [75, 77, 96] and oceanic microbiomes [103] and expands the scope of the pan-global microbiota.

Data availability

Sequencing data are accessible in the NCBI Sequence Read Archive (SRA) under BioProject numbers PRJEB42754 (<https://www.ncbi.nlm.nih.gov/search/all/?term=PRJEB42754>) for amplicon sequencing and PRJNA694999 (<https://www.ncbi.nlm.nih.gov/bioproject/?term=PRJNA694999>) for metagenomes.

Supplementary information is available for this paper.

Figure Legends

Fig 1 | A globally distributed survey of microbial communities in the atmospheric boundary layer, free troposphere and underlying soil. a) Locations are indicated by green boxes where: 1, Canada; 2, Mongolia; 3, Spain; 4, Japan; 5, California, USA; 6, Kuwait; 7, Hilo, Hawaii, USA; 8; Mauna Kea, Hawaii, USA; 9, Singapore; 10, Coral Sea; 11, Namibia; 12, Chile; 13, South Africa; 14, Australia; 15, Uruguay; 16, New Zealand; 17, Southern

Ocean; 18, Antarctica. Meta-data for each location are shown in Supplementary information. Back trajectories are shown for near-ground air (blue lines) and high-altitude air (red lines), The survey comprised 596 biologically independent replicates. **b)** Inter-domain abundance of reads for metagenomes ($n=120$). Other eukaryotes included all microbial eukaryotes, viruses were not a specific target of our study and so this likely includes only cell-associated viruses, HA air denotes high-altitude air; NG air denotes near-ground air.

Fig. 2 | Bacterial and fungal assemblages are taxonomically structured. a) Relative abundance of bacterial classes in soil ($n = 79$), near-ground air (NG air) ($n = 437$) and high-altitude air (HA air) ($n = 13$). **b)** Alpha diversity metrics for bacteria. **c)** Bacterial assemblage dissimilarity (Jaccard Index) by location (3-D visualizations are presented in Fig. S24). **d)** Modelled nestedness estimates for bacteria were based upon networks constructed for each habitat and location (Fig. S27). **e)** Relative abundance of fungal classes in soil ($n = 79$), near-ground air (NG air) ($n = 437$) and high-altitude air (HA air) ($n = 13$). **f)** Alpha diversity metrics for fungi. **g)** Fungal assemblage dissimilarity (Jaccard Index) by location (3-D visualizations are presented in Fig. S24). **h)** Modelled nestedness estimates for fungi were based upon networks constructed for each habitat and location (Fig. S27).

Fig. 3 | Bacterial and fungal assemblages are recruited from local and global sources. a) Shared bacterial and fungal taxa among habitat types within and between locations. **b)** Source contribution by climate for observed bacterial and fungal diversity in air, values averaged for each source to mitigate sample size effects (Bacteria $n=529$, Fungi $n=444$). Locations ordered by latitude from North to South: 1, Canada; 2, Mongolia; 3, Spain; 4, Japan; 5, California, USA; 6, Kuwait; 7, Hilo, Hawaii, USA; 8; Mauna Kea, Hawaii, USA; 9, Singapore; 10, Coral Sea; 11, Namibia; 12, Chile; 13, South Africa; 14, Australia; 15, Uruguay; 16, New Zealand;

17, Southern Ocean; 18, Antarctica. HA air denotes high-altitude air; NG air denotes near-ground air.

Fig. 4 | Assemblages possessed stress response and metabolic genes relevant to survival in the atmosphere. **a)** Heatmap summarising functional metagenomic profiling of targeted stress-response and metabolic genes by habitat type ($n = 120$). Full data for all replicates at each sample-location combination is shown in Supplementary information Fig. S31. **b)** Distribution of stress-response and metabolic genes by climatic region, with all locations globally pooled by climate ($n = 120$). Oxid. Stress denotes oxidative stress; Trace gas met. denotes trace gas metabolism. HA air, high-altitude air; NG air, near-ground air.

Fig. 5 | Atmospheric taxonomic and functional diversity are correlated with macroclimate and atmospheric transit abiotic variables. **a)** Correlation of location-specific macroclimate factors and abiotic stressors during transit (Supplementary information: Fig. S2) with biotic traits of atmospheric assemblages. **b)** Correlation of location-specific macroclimate factors with biotic traits of soil assemblages. Blue circles denote positive correlations and red circles denote negative correlations. Circle colour intensity and size denote magnitude of correlation. Correlations were significant at $P = <0.05$. Asterisks denote correlations that were significant after Bonferroni Correction (single asterisk $P = 0.05$, double asterisk $P = 0.003$). MAT, mean annual temperature; MAP, mean annual precipitation; RH, relative humidity; UV, ultraviolet radiation. Abundance, qPCR estimated gene copy number; Richness, Chao1 estimation from rRNA gene diversity.

Supplementary methods

Table S1 | Globally distributed sampling locations included in the study. Locations are ordered by latitude from north to south. The sampling campaign retrieved 596 air and soil samples from 18 locations spanning all major climatic regions and continents plus two oceans and included negative controls for every location (Decontamination of environmental sequence data). Several dryland (desert) locations were incorporated because they comprise the most abundant terrestrial biome on earth and are also the single largest natural source of particulate emissions to the atmosphere [1]. The Southern Hemisphere was sampled during April-May 2019 and the Northern Hemisphere during June-July 2019. The two circumnavigations encompassed every major climatic biome and included high and low growing seasons. Oceanic and remote land samples were retrieved during independent voyages (May 2017 – June 2018) using the same sampling methodology and samples from the two previously interrogated locations were re-sequenced for this study [2, 3].

Location No	GPS (decimal degrees)	Atmospheric cell [^]	Climate ⁺	Altitude (m AMSL)	Country/Ocean	Surface cover

[^] Atmospheric cells describe the prevailing air movement in latitude-defined cells: Polar Cells occur at 60° and higher latitudes, Ferrel Cells at mid-latitudes between 30-60°, and Hadley Cells at latitudes of 30° and below.

⁺ Climate codes follow the Köppen climate classification, major delineations were: A, tropical; B, dry; C, temperate; D, continental, E, polar [4].

*This location was affected by a Sahara Desert atmospheric dust intrusion during sampling.

Supplementary notes on environmental metadata

Long-term macroclimate variables for each sampling location (Table S1) were retrieved from public databases: mean annual precipitation and mean annual temperature [5], Köppen-Geiger climate classifications [6], growing season that defined the time period when photoautotrophy can occur [7]. Other local variables were recorded using handheld devices: Temperature (°C), relative humidity (%), wind speed (m/S) and wind direction (Kestrel Meters, USA); Particulate matter (PM 2.5 and PM 10.0) (HoldPeak, China). Full metadata for each sampling location and event are available upon request at <http://atmospheric-microbiome.com/>. In order to identify back trajectory and environmental variables encountered by microorganisms during their transit in air towards each sampling location, we obtained data from the NOAA HYSPLIT-model, and long-range trajectories and abiotic variables were estimated using the NOAA Global Data Assimilation System (GDAS) [8]. The depths of the atmospheric boundary layer (mixing depths) were calculated from meteorological fields of the GDAS model that was used to calculate the back trajectories (Fig. S1). Fourteen day back trajectories of air masses for each sampling time were generated because this is the estimated maximum residence time for microorganisms in the troposphere (Fig. S2) [9]. The following variables were calculated at intervals along each tropospheric transport path from the HYSPLIT models: altitude (m above ground level, AGL), wind speed (m/S), direction, temperature (°C), Relative humidity (%), solar irradiance (W/m²), precipitation events, and transit duration over land or ocean surface (Fig. S2). Data was processed using ArcGIS Pro, version 2.6 (<https://www.esri.com>). Points were plotted on WGS 1984 Web Mercator coordinate system with date line wrapping and climate mapping at 1km resolution [6].

Fig. S1 | Mean transit altitudes for sampled air. Blue denotes near-ground sampling (NG air), red denotes high-altitude aircraft sampling above the atmospheric boundary layer (HA air), bar indicates depth of the atmospheric boundary layer. Locations: 1, Canada; 2, Mongolia; 3, Spain; 4, Japan; 5, California, USA; 6, Kuwait; 7, Hilo, Hawaii, USA; 8, Mauna Kea, Hawaii, USA; 9, Singapore; 10, Coral Sea; 11, Namibia; 12, Chile; 13, South Africa; 14, Australia; 15, Uruguay; 16, New Zealand; 17, Southern Ocean; 18, Antarctica. All altitudes and depths are shown as metres above local ground level (AGL).

Fig. S2 | Atmospheric variables encountered by microorganisms during transit to each sampling location.
a, Temperature. **b**, Solar flux. **c**, Relative humidity. **d**, Transit over land/ocean. **e**, Transit altitude. **f**, Transit velocity.

Supplementary notes on sample recovery

Recovery of bulk phase air was achieved using three Coriolis μ high-volume impingement devices (Bertin Instruments) operated concurrently. This device has been shown to perform well against other samplers [10]. All equipment was transported between locations in sterile containers and bags. Each device was dis-assembled and contact surfaces soaked for one hour with 1.5% v/v sodium hypochlorite (NaClO) followed by three washes of Milli-Q H₂O prior to and after each sampling in order to minimise contamination from cells or nucleic acids. All apparatus and work surfaces used during sampling and sample processing were also cleaned in this way prior to use. All operators wore surface sterilised nitrile gloves during field collections. Randomised collection cones were assembled into the devices without activating the air pump, and these were used as the negative sampling controls at each location. Additional control samples for potential human contamination were provided via swabs from the inside of anonymised used nitrile gloves (human operator controls).

Samplers for near ground air (NG air) were located on tripods 1.5m above the ground and 3m apart from each other at each sampling location and all inlets were aligned facing prevalent local wind direction. Samplers were only approached from downwind during operation. For high altitude air (HA air) the three samplers were fixed with the air inlet port protruding outside the aircraft cabin either through a window or open door, and each sampler was 1-2m apart depending upon cabin configuration for aircraft at each sampling location. Aircraft followed a flightpath circling above the corresponding near ground sampling location at an altitude of 2,000m which was above the estimated depth of the atmospheric boundary layer for the sampled locations [11]. Aircraft-mounted air samplers were operated only whilst the aircraft was at the desired 2,000m altitude.

Bulk air for both near ground and high altitude samples was recovered at 300 L/min⁻¹ and particulates recovered after cyclonic deceleration into a sterile phosphate-buffered saline (PBS) impingement medium in each collection cone. Each device was used to collect discrete 18 m³ air samples hourly as this volume has been shown to result in recoverable environmental DNA [3]. Surface samples were recovered hourly between 10:00 – 16:00 hrs daily and sample collection flights were carried out within the same time period for each sampling event, and then processed immediately by syringe filtration onto a 25 mm polycarbonate filter with 0.2 μ m pore size and preserved in 0.5 mL of DNA/RNA Shield (Zymo Research, USA) at ambient temperature during transit and then frozen at -20° C until processed for DNA extraction in the laboratory.

At each location undisturbed surface soil or sediment samples (upper 2cm soil captured in sterile 50 mL screw-cap tubes) were also collected from the base of each Coriolis μ device as well as 25 m away in 120° intervals from the point of sampling. In recognition of inherent soil heterogeneity each sample comprised five subsamples that were mixed and then resampled to yield each sample for analysis. For each sample 0.5 g was preserved for DNA extraction in 0.5 mL of DNA/RNA Shield (Zymo Research, USA) at ambient temperature during transit and then frozen at -20° C until processed for DNA extraction in the laboratory. The remaining sample fraction was archived. It was recognised that soil is not the primary reservoir for terrestrial fungal diversity but in the absence of a practical means to globally sample the diversity of other fungal substrates we accepted this limitation to the study.

DNA extractions from samples were performed under strict microbiological biosafety conditions in randomised sample batches, and each with discrete laboratory controls to assess potential laboratory or reagent contamination. Each sample tube was processed individually in order to avoid potential cross-contamination between samples due to micro-droplet transfer. All sequencing outputs were evaluated for batch effects, contamination and spatial and temporal auto-correlation as described in Decontamination of environmental sequence data (see below). Environmental DNA was recovered from filtered air and soil samples using a CTAB-based manual extraction protocol optimised for low biomass samples [3]. DNA yield was quantified using the Qubit 2.0 Fluorometer (Invitrogen, USA) and samples were then stored at -20 °C until processed. DNA yield per m³ air or per gram of soil were used as a proxy for total biomass [12], although estimates between soil and air are not directly comparable due to different substrate volumes and composition.

Supplementary notes on use of Null models

Models

Null models are widely used by ecologists to detect non-random patterns in data matrices. These models generally require a randomization of observed data subjected to some constraints. The constraints should reflect the hypotheses under investigation [13–15]. The typical data matrix analysed by ecologists are species by site tables and tables that represent interactions between different groups of species (for example plant-pollinator or plant-root symbiont networks). Classical ecological null models are constructed by constrained permutations, which usually fix some general property of the data matrix such as the column or row margins [15–17]. A metric quantifying the pattern under investigation is then calculated both on the observed data matrix and the randomly generated matrices. Using the logic of null models, the difference between the observed metrics and the metrics in the randomised null matrices is expressed as the z -score of the metric, say metric X , as:

$$z_X = \frac{X(\mathbf{O}) - \langle X \rangle}{\sigma(X)} = \frac{X^* - \langle X \rangle}{\sigma(X)}$$

Where $\mathbf{O}$ is the observed data matrix, X^* is the observed value of the metric and $\langle X \rangle$ and $\sigma(X)$ are the expected value and standard deviation in the ensemble of the permuted matrices. If $\langle X \rangle$ and $\sigma(X)$ describe a normal distribution, the probability of observing a difference beyond two standard deviations just by chance would be roughly 0.05, but if the distribution is not normal an operational p -value < 0.05 can be calculated following classical null modelling [13]. As explained in the main methods, we did not use permutations of the raw data to construct our null models. The reason is that producing a large number of randomly rewired matrices using permutations leads to a set of biased null model matrices, if the original matrix is heterogeneous (e.g. some taxa are much more widespread than others) and sparse [18, 19]. Local randomization algorithms risk sampling the set of null, random matrices non-uniformly, which means that the estimates of the metrics measured on the data matrix is not guaranteed to correspond to the correct theoretical expectation. Given all these issues, which would likely affect a classical null model analysis of our data set, we used the so-called network canonical ensemble, a model belonging to the set of methods known as the statistical mechanics of network. The most complete reference for our approach is in the book by Squartini & Garlaschelli 2017 [20]. Briefly, we interpreted the taxon by location data matrix as a binary bipartite network that describes the occurrence of each taxon at each location. We used the number of taxa at each location or, conversely, the number of locations in which each taxon was found as the constraining vector for the construction of the null model ensemble. The null model matrices will thus be fully random in terms of which taxon is found at each location, which is central to our hypothesis of a non-randomly structured air microbiome. At the same time, the number of taxa per location and also the number of locations in which each taxon is found is, on average, the same in the null models and in the observed matrices. This is

important, because it means that deviations of observed data from the null models will be affected solely by the taxonomic composition of the assemblage. As it can be easily shown following the derivations [20], the Hamiltonian of the graph corresponding to our model would then be

$$H(\mathbf{A}, \boldsymbol{\theta}) = \sum_i \theta_i k_i(\mathbf{A}) = \sum_i \sum_{j < i} (\theta_i + \theta_j) a_{ij}$$

for a general binary matrix, and the probability distribution of each occurrence in the matrix

$$P(\mathbf{A}|\boldsymbol{\theta}) = \prod_i \prod_{j < i} p_{ij}^{a_{ij}} (1 - p_{ij})^{1-a_{ij}}.$$

This solution can easily be reparametrized to describe a binary bipartite graph [21]. The probability distribution $P(\mathbf{A}|\boldsymbol{\theta})$ is the correct (i.e. it maximises entropy) probability distribution for each taxon randomly occurring in each location, subject to the constraints given by the number of locations in which that taxon can be found, and the number of taxa found in each location. The parameters of the distribution can be estimated using maximum likelihood methods [22] (described in the Methods). The probability distribution is then sampled [23], to generate the desired number of randomised matrices (we sampled 999 matrices) and construct the null model. As the probability distribution is analytically derived for each of the three types of samples we analysed (soil, near ground and high elevation air), each type of sample (soil, NG air and HA air) has its own baseline or null model.

Metrics

The metrics we tested in the null models were NODF, a metric of nestedness, and the Jaccard index. There is a vast, and often lively debated literature on the property of nestedness. Nested pattern have been defined as (quote) “[nested patterns] are those in which the species composition of small assemblages is a nested subset of larger assemblage” [24]. This applies also to randomly assembled communities and so a null model is needed to test whether nestedness pattern are not random. Assume the microbial composition at each location is completely random and just reflects recruitment of the most abundant taxa from the regional pool. Then, any local community that randomly recruits a relatively small number of taxa will form a subset of the local communities that randomly happen to recruit a relatively large number of taxa. However, if different groups of local communities or, also, individual local communities, are characterised by a particular and unique taxonomic composition, with some taxa that specifically occur only at certain locations and others that occur at other locations, observed nestedness will be much lower than expected under a null model that fully randomise taxa composition.

Our second metrics, the Jaccard index on presence/absence data, quantifies pairwise community dissimilarity. The higher the index the lower the number of taxa shared by the two compared locations. One can thus calculate the average dissimilarity of a taxon by location matrix, which we did both for the observed and null model matrices. Our results (Fig. 2) showed that bacterial (Fig. S4) and fungal communities (Fig. S5) in air were more dissimilar than expected under the null model. Fungi in soil showed the same difference. Instead, bacteria in soil were more similar than expected under the null model.

Fig. S4 | Jaccard network null model for bacterial ASVs.

Fig. S5 | Jaccard network null model for fungal ASVs.

There are several possible explanations for convergence and divergence of taxonomic composition relative to the baseline provided by a stochastic null model (e.g. [25–29]). Soil appeared to have “homogenised” ASVs and also at higher rank community composition (not shown) relative to the null model. This could be due to selection forces such as environmental filtering combined with limited dispersal, as discussed in the main text. In contrast, Air made ASVs and also higher rank taxa composition more heterogeneous than in the null model. This type of compositional divergence, too, can be due to selective forces but with the environmental conditions of the locations varying to a large extent between locations, which diversifies the composition of communities across locations. The explanations we are offering for these patterns of compositional dissimilarity observed in air and soil remain hypotheses to be tested in the future but the Jaccard pattern, together with NODF demonstrates the non-random structure of the air microbiome in terms of the distribution of taxa across the network of locations of this study.

Table S2 | Functional genes targeted in the metagenomics inquiry of air and soil. A suite of respiratory genes was used as a general marker of potential for metabolically active taxa, and targeted metabolic and stress response genes were selected based upon substrates and stressors encountered in the atmospheric habitat.

Trait	Protein	Gene
Respiration	ATP synthase	<i>atpA</i>
	Cytochrome cbb3 oxidase	<i>ccoN</i>
	Cytochrome aa3 oxidase	<i>coxA</i>
	Cytochrome bd oxidase	<i>cydA</i>
	Cytochrome bo3 oxidase	<i>cyoA</i>
	NADH-ubiquinone oxidoreductase subunit F	<i>nuoF</i>
	Succinate dehydrogenase/fumarate reductase	<i>sdhA/frdA</i>
Carbon fixation	Ribulose 1,5-bisphosphate carboxylase/oxygenase	<i>rbcL</i>
Nitrogen fixation	Nitrogenase	<i>nifH</i>
Phototrophy	Photosystem I reaction centre protein	<i>psaA</i>
	Photosystem II reaction centre protein	<i>psbA</i>
	Microbial rhodopsin	<i>RHO</i>
Atmospheric trace gas metabolism (carbon monoxide, hydrogen, methane, isoprene)	Aerobic carbon monoxide dehydrogenase	<i>coxL</i>
	Hydrogenase	<i>Fe</i>
	Hydrogenase	<i>FeFe</i>
	Isoprene oxidation gene	<i>isoA/mmoX</i>
	Soluble methane monooxygenase	<i>mmoX</i>
	Particulate methane monooxygenase	<i>pmoA</i>
cold-shock	Cold shock protein A	<i>cspA</i>
	Cold shock protein B	<i>cspB</i>
	Cold shock protein G	<i>cspG</i>
	Cold shock protein I	<i>cspI</i>
Oxidative stress	Protein-methionine sulfoxide reductase	<i>msrP</i>
	Protein-methionine sulfoxide reductase	<i>msrQ</i>
Sporulation	Sporulation protein 0A	<i>spo0A</i>
Starvation/stationary phase	DNA-protection during starvation protein	<i>dps</i>
	Outer membrane protein	<i>slp</i>
UV response/repair	Deoxyribodipyrimidine photo-lyase	<i>phrB</i>
	UvrABC system protein A	<i>uvrA</i>
	UvrABC system protein B	<i>uvrB</i>
	UvrABC system protein C	<i>uvrC</i>
Ice nucleation	Ice nucleation protein A	<i>inaA</i>
	Ice nucleation protein X	<i>inaX</i>
	Ice nucleation protein W	<i>inaW</i>
	Ice nucleation protein Z	<i>inaZ</i>

Decontamination of environmental sequence data

Here we present supporting evidence to demonstrate our decontamination pipeline resulted in effective removal of contaminants and did not adversely impact the observed ecological patterns for our data. Our approach to decontamination adopted and fully reports a thorough multi-step decontamination protocol as per recommended best practice [30–32]. The decontamination of our sequence data was an integral part of our wider approach to careful sampling of ultra-low biomass atmospheric samples and soils (Fig. S6).

Fig S6 | Summary of steps taken to minimise contamination during environmental DNA recovery and sequencing from low biomass air and soil samples. QC denotes quality control, ASV denotes amplicon sequence variant, NTU denotes nearest taxonomic unit used for taxa assignment from metagenomes.

Our close attention to careful field sampling and laboratory workflow resulted in very low read numbers for our control samples compared to environmental samples (Fig. S7). A very small number of 16S rRNA gene sequencing controls ($n = 3$) with higher reads did not identify significantly more ASVs for removal, rather they largely comprised higher read numbers of ASVs that also occurred in other controls. We regard this as an important part of the heterogeneity encountered in environmental microbiology and so we retained these controls in our decontamination pipeline. Due to our careful attention to randomization and replication the few controls with higher reads did not impact the ecological patterns presented for the filtered data.

Fig. S7 | Sequencing read depth for controls and environmental samples. a, Bacteria read depth (controls: n = 35; samples: n = 529). **b,** Fungi read depth (controls: n = 35; samples: n = 444). **c,** Metagenomes read depth for controls (n = 3, pooled by type from 35 independent control samples) and samples (n = 120). Boxplots indicate median (line) and interquartile range (boxes).

We report the removal of reads at each of the decontamination steps for our amplicon sequence data as per recommended best practice (Table S3) [31]. Sequencing studies of dilution series for mock communities have shown that there is an unavoidable increase in contaminant signal as starting template decreases [33]. This and other studies, e.g. [30], indicate that the percentage of contaminants detected during dilution series to obtain template DNA levels similar to those in our study were comparable or higher (approx. 50-80% in mock communities) to those we observed for our environmental samples, thus supporting that the level of contaminants we encountered was not unexpectedly high for the ultra-low biomass habitats being interrogated. Furthermore, the proportion of reads removed from our dataset is consistent with the range in published reports for other ultra-low biomass environmental studies where numbers have been disclosed, i.e. Sheik *et al.* (2018) concluded approximately 27% of OTUs in deep biosphere samples were contaminants [34], Els *et al.* (2019) removed 40% of amplicon OTUs during decontamination [35], Kiledal *et al.* (2021) removed 85% of amplicon reads during decontamination [36].

We report the diversity of ASV removed at each stage of our decontamination process (Fig. S9). Untargeted sequence removal included reads affiliated with chloroplasts, mitochondria and other non-target organisms. The R package decontam was applied using a stringent statistical threshold for frequency (0.1) and/or prevalence (0.5). Control removal included any taxa occurring in any of the field blanks, laboratory blanks or swabs of human operator gloves being filtered from all samples. Finally, the filtering of named genera targeted any remaining taxa commonly reported as human-associated contaminants (n = 21 genera) in published meta-analyses of ultra-low biomass microbiomes [30, 31].

Fig. S8 | Comparison of pre-decontamination taxonomic composition of bacteria in controls and samples. Bubble plots illustrating genus-level taxonomic composition of bacteria in controls and samples prior to decontamination workflow. Bubble sizes indicate relative abundance. Note that absolute abundance varied due to lower reads in controls versus samples (Fig. S7). Values are the mean of all replicates for any given treatment. NG air = near-ground air, HA air = high-altitude air.

Fig. S9 Comparison of pre-decontamination taxonomic composition of bacteria in controls and samples. Bubble plots illustrating genus-level taxonomic composition of fungi in controls and samples prior to decontamination workflow. Bubble sizes indicate relative abundance. Note that absolute abundance varied due to lower reads in controls versus samples (Fig. S7). Values are the mean of all replicates for any given treatment. NG air = near-ground air, HA air = high altitude air.

Table S3 | Total percentage of sequenced reads removed from each step of the decontamination process. NG air denotes near-ground air and HA air denotes high-altitude air.

16S rRNA gene sequencing decontamination (% of total reads removed from previous step)			
	Soil	NG air	HA air
Untargeted (%)	0.71	10.84	6.35
Decontam (%) ⁺	9.67	21.65	21.24
Control removal (%) [#]	4.99	9.57	8.43
Genus-level filtering (%) [^]	0.22	0.9	1.58
Total removed (%) ⁼	15.58	42.98	37.60
ITS sequencing decontamination (% of total reads removed from previous step)			
	Soil	NG air	HA air
Untargeted (%)	1.0	0.07	0.05
Decontam (%) ⁺	23.28	42.98	51.25
Control removal (%) [#]	3.24	12.39	10.09
Genus-level filtering (%) [^]	0.13	0.06	0.03
Total removed (%) [@]	27.55	55.49	61.44

⁺ The removal of suspiciously frequent and/or prevalent ASVs using the R package decontam resulted in higher numbers of removed ASVs from near-ground air and high-altitude air samples due to the ultra-low biomass of samples and unavoidable increase in contaminant signal [30, 31].

[#] ASVs occurring in any of the field sampling controls, human operator controls or laboratory reagent controls were removed from all samples regardless of whether they were encountered in location-specific or habitat-specific controls where a given sample was recovered.

[^] Whilst our decontam and control removal steps removed most common human and reagent contaminants, we also applied an additional subtractive filter to remove any remaining suspected human-associated contaminants. We targeted the following bacterial genera: *Bacteroides*, *Bifidobacterium*, *Corynebacterium*, *Cutibacterium/Propionibacterium*, *Escherichia*, *Faecalibacterium*, *Haemophilus*, *Klebsiella*, *Lactobacillus*, *Listeria*, *Moraxella*, *Neisseria*, *Porphyromonas*, *Prevotella*, *Shigella*, *Salmonella*, *Staphylococcus*, *Streptococcus* and *Veillonella*. We also removed ASV affiliating with the human-associated fungal genera *Candida* and *Malassezia*. We acknowledge that some of these genera, e.g. *Klebsiella*, *Lactobacillus*, *Listeria*, *Candida* (together approx. 0.1% reads in our study) may also support environmental taxa but we chose to take a cautious approach and remove all ASVs in the genus because most of these ASVs in our study affiliated to human-associated taxa or it was uncertain from database metadata if they were genuine environmental taxa.

⁼ Soils were highly heterogenous and soil biomass was positively correlated with retained reads post-filtering. In all but the most extreme desert mineral soils the average occurrence of potential contaminants was ~1% of bacterial and ~5% of fungal quality-filtered reads (Figs S10, S11).

[@] Relatively high read removal for ITS reads may in part reflect the nature of fungal spore emission and this is impossible to deconvolute from the algorithm for suspicious frequency/prevalence in decontamination software. In order to be cautious in our approach, we report the diversity of all removed taxa so these data are not lost from the study.

A similarly rigorous process was applied to our metagenomes:

Shotgun metagenome decontamination (% of total reads removed from previous step)			
	Soil	NG air	HA air
Contaminant contig mapping (%)	4.86	5.33	4.21
Decontam (Bacteria) (%)	0.29	1.03	1.5
Genus-level filtering (Bacteria) (%)	0.61	1.56	1.13
Decontam (Fungi) (%)	0.069	0.47	1.52
Genus-level filtering (Fungi) (%)	0.0002	0.0008	0.014
Total removed(%)	5.83	8.39	8.38

Fig. S10 | Relationship between soil biomass and bacterial reads retained post-filtering. Encounter with potential contaminants in globally sourced soils displayed clear positive correlation with soil biomass (Pearson correlation coefficient $r(77) = 0.54$, $P = 2.4 \times 10^{-7}$). The variation reflected the globally distributed soil habitats in our study. In general terms the more “typical” temperate and tropical soils had very low contaminants (average approx. 1%) using our stringent protocol, whereas for Antarctic and extreme desert soils the values were markedly higher and more variable and this accounts for the overall average for all global soils of 14.87% post-removal of non-target reads (Table S3).

Fig. S11 | Relationship between soil biomass and fungal reads retained post-filtering. Encounter with potential contaminants displayed clear positive correlation with soil biomass (Pearson correlation coefficient $r(68) = 0.65$, $P = 1.18 \times 10^{-9}$). The variation reflected the globally distributed soil habitats in our study. In general terms the more “typical” temperate and tropical soils had very low contaminants (average approx. 5% for fungi) using our stringent protocol, whereas for Antarctic and extreme desert soils the values were markedly higher and more variable and this accounts for the overall average for all global soils of 26.55% for fungi post-removal of non-target reads (Table S3).

Fig S12 | Rarefaction curves for amplicon sequence data. a, Bacteria (soil ($n = 79$), near-ground air (NG air) ($n = 437$) and high-altitude air (HA air)). **b**, Fungi (soil ($n = 70$), near-ground air (NG air, $n = 363$) and high-altitude air (HA air, $n = 11$)). Sampling curves are shown for sequence data after subtractive filtering by the comprehensive decontamination steps. The number of reads for bacteria, after filtering (final data) was: Min: 1,303, Median: 18,877, Mean: 23,114, Max: 174,577; and for fungi, after filtering (final data) was: Min: 1,106, Median: 14,238, Mean: 18,187, Max: 116,859.

Fig S13 | Rarefaction curves for Metagenomes ($n = 120$). NG air denotes near-ground air and HA air denotes high-altitude air.

Fig. S14 | Taxonomic identity of reads removed during the decontamination process. Taxonomic composition of removed reads for the 10 most abundant classes at each decontamination step (a) and overall (b) bacterial amplicon data; Taxonomic composition of removed reads for the 10 most abundant classes at each decontamination step (c) and overall (d) fungal amplicon data. Note: Cyanobacteria removed reads affiliated to chloroplasts, a portion of Alphaproteobacteria reads removed affiliated to mitochondria.

We next performed a post-hoc analysis of our filtered dataset after decontamination to estimate the effectiveness of the multi-step subtractive filtering process and identify any remaining ASVs that may represent potential residual contaminants, as well as identify any evidence for cross-contamination between sample types. In order to focus on unequivocal contamination events, we subsampled the data to 1000 reads per sample and removed taxa that were present in fewer than 10 samples. FastSpar correlation scores and their P values were determined for genus-level taxa and then heatmaps were used to visualise clusters indicative of potential artefacts (Fig S15). Next, taxonomic composition of each cluster were checked for frequency and prevalence of the taxa throughout the dataset. For a cluster to be identified as an artefact suitable for subtraction we applied the following criteria: i) It should align with metadata such as processing batch, sequencing batch, or reagent lot numbers, ii) It should be implausibly consistent between samples, for example if it spans multiple ecological locations, iii) it should be extremely rare beyond the artefact itself.

The analysis revealed a small number of clusters in the bacterial and fungal datasets and weak correlation blocks overall. This indicates a low possibility of exogenous contaminant since taxa arising from a common source would correlate more strongly than real ecological associations. There was no evidence for batch effects (i.e. correlation blocks did not match up with processing batch, sequencing batch, or reagent lot numbers) but a small number of genera displayed clustering indicative of potential residual contamination. A cluster comprising *Ampullimonas*, *Rhizobacter*, *Tardiphaga*, *Variovorax*, and unclassified *Methylophilaceae* appeared to form a tightly correlating pattern that was not tied to geographic origin and so they are likely to be residual contaminants. Additional weak clusters yielded inconclusive evidence for potential residual contamination from *Acidovorax*, *Bradyrhizobium*, *Pseudomonas*, *Ralstonia*, and *Sphingomonas*. The latter genera contain ASVs that were removed during our decontamination steps but they also contain known environmental taxa and so removing them at genus level was deemed imprudent. For the fungi a single correlation block affecting 88 samples was identified as worthy of further scrutiny, but since these samples all originated from marine and maritime locations in the southern hemisphere it was concluded this likely represented a valid separation from other samples geographically and by ocean-land site separation.

We identified all ASVs in our filtered bacterial dataset that affiliated within the genera identified as potentially suspicious from this analysis (Fig. S16). Most of these formed a very low percentage of overall diversity with the exception of *Ralstonia*, where a small number of ASVs occurred with higher frequency in some high-altitude air samples. In view of the overall low number of potential residual contaminants, that they affiliated with genera that have known environmental taxa as well as commonly encountered contaminants, and in order to preserve the clear step-wise decontamination process was applied identically across samples; we chose not to perform further removal of these ASVs, although we report their taxonomic affiliation so that this can be used to nuance our data. The filtered fungal dataset revealed no potential residual contaminants.

Fig. S15 | Post-decontamination check for residual contaminants. Heatmaps visualise taxon correlation clustering for a) bacterial and b) fungal genera.

Fig. S16 | Taxonomic composition of potential residual contaminants. Data shown as a fraction of the filtered bacterial datasets from different habitats. NG Air = near-ground air, HA Air = high-altitude air.

We further analysed our data to examine the potential for batch effects (cross contamination) because this is of particular importance when sampling habitats with highly differing biomass such as air and soil. We also examined our data for potential signals of temporal or spatial auto-correlation.

Several steps were taken to minimise the potential for cross contamination:

1. Soil and air were sampled separately in time (i.e. soil was collected immediately after each air sampling) and in terms of potential cross-contact (i.e. separate field equipment and processing for soil and air). All samples (i.e. both soil and air) entered the laboratory in the same state in separate sealed and surface-sterilised sample tubes as a mixture in nucleic acid preservative solution (i.e. no free soil particulates were introduced to the laboratory).
2. The processing of all samples was fully randomised for location and habitat type. The randomised workflow involved some batches where both air and soil samples were processed in the same batch and others where air samples only were processed, but we conducted two very important steps to check for potential cross contamination: i) We adopted a workflow where for every batch, each sample tube was processed individually within a BSL2 flow hood. This means that at any given time during laboratory work only a single sample tube was opened during processing to reduce the chance of cross-contamination (the main source of cross-contamination is thought to be micro-fluid splashes between samples). No multiplexing was employed during pipetting. We believe this was a necessary although extremely laborious step to avoid cross-contamination. ii) We conducted statistical tests to determine batch-type did not result in significantly different estimates, i.e. there was no evidence for cross-contamination between soil and air samples. Matching samples (from same location and same sample types but differing in sequencing batches which had either air samples only or with air and soil samples) showed significant concordance and low sum of squared errors, thus high goodness of fit (Bacteria: $n = 250$, $m^2 = 0.043333$, $P = 0.001$; Fungi $n = 186$, $m^2 = 0.049571$, $P = 0.001$) between their ordination coordinates (PCoA with Hellinger distance) (Fig. S12). This suggests low influence within each sequencing batch (the dissimilarities of the communities were preserved regardless of other samples in the sequencing batches). This was also supported by a Mantel test of the community distances (Bacteria: $n = 250$, $r = 0.818$, $P = 0.001$; Fungi $n = 186$, $r = 0.915$, $P = 0.001$). These findings were also supported by our post-decontamination correlation analysis above (Fig. S15), where there it was clear that cross contamination between air and soil samples had been successfully avoided.
3. In addition, controls were included at all sampling and lab processing stages and these were included in the randomised workflow to check for sampling and laboratory reagent contamination (i.e. controls were randomly incorporated into each batch). We also employed other stringent measures to avoid contamination such as full PPE for operators, bleach-sterilization of all laboratory surfaces and equipment contact surfaces, and UV illumination of workstations when not in use.
4. Our amplicon and metagenome sequencing devices were located in different laboratories and yielded comparable diversity trends across all samples, which we confirmed statistically using Procrustes analysis (Bacteria $M^2 = 0.76$, correlation = 0.49, $p = 0.001$; Fungi $M^2 = 56$, correlation = 0.66, $p =$

0.001). This provided evidence that cross-contamination during sequencing was highly unlikely due to our randomised workflow.

Matching samples (from same location and same sample types but differ in sequencing batches which had either air sample only or with air and soil samples) showed significant concordance and low sum of squared errors, thus high goodness of fit (Bacteria: $n = 250$, $m^2 = 0.043333$, $P = 0.001$; Fungi $n = 186$, $m^2 = 0.049571$, $P = 0.001$) between their ordination coordinates (PCoA with Hellinger distance). This suggests low influence within each sequencing batch (the dissimilarities of the communities were preserved regardless of other samples in the sequencing batches). This was also supported by a Mantel test of the community distances (Bacteria: $n = 250$, $r = 0.818$, $P = 0.001$; Fungi $n = 186$, $r = 0.915$, $P = 0.001$). It was clear from ordinations that sampling date did not affect location and habitat-specific clustering and so temporal auto-correlation was discounted as a confounding factor (Bacteria $n = 449$, Fungi $n = 365$) (Fig. S17). We also performed checks using PCNM to statistically discount the effects of spatial auto-correlation on our findings [37, 38]. Our sampling design was dominated by very large distances that separated the main locations across the major biomes and continents we sampled across the globe. Due to the lack of hierarchical structure this design was not intended to account for smaller spatial scales such as within continents or between locations within the same continent. Because of this reason, when we applied PCNMs to our dataset, the results indicated that latitude and longitude were the major spatial correlates of the multivariate distribution displayed, as shown in the Results where samples clearly clustered by geographic location. The simple linear effect of latitude and longitude thus dominated as a simple expression of the large distance between our sampling locations, and the resulting PCNMs (eigenvectors) extractable from our distance matrix accounted for such a small amount of variance that we eventually excluded these vectors after our preliminary check for autocorrelation. We therefore also calculated and reported distance decay and co-occurrence analysis to add another layer of support that spatial auto-correlation was not a significant confounding factor on our observations. Our post-decontamination correlation plot for location at genus level (Fig. S15) also revealed no patterns that support the existence of strong spatial auto-correlation independent of the differences expected and observed due to different climate and habitat.

We then plotted visualisations of our data to illustrate ASV removed from each location and habitat type (Fig. S18), and the diversity of filtered ASV in all samples pre- and post-decontamination (Figs S19, S20). We then tested that our robust decontamination protocol did not have a significant impact on the strong ecological patterns by habitat type and location as highlighted in our manuscript (Fig. 2). We performed ordinations (tSNE based on Hellinger Distances) for the community separately for raw and filtered data (i.e. pre- and post-decontamination) (Fig. S21). This was confirmed with strong and significant correlations for both Procrustes and Mantel tests based on Pearson's product-moment correlation for congruence for bacteria (Procrustes $m^2 = 0.089$, correlation = 0.955, $P = <0.01$ and confirmed by Mantel statistic $r = 0.744$, $P = <0.01$); and fungi (Procrustes $m^2 = 0.083$, correlation = 0.958, $P = <0.01$ and confirmed by Mantel statistic $r = 0.901$, $P = <0.01$).

Fig. S17 | Evaluation for batch effects and temporal auto-correlation in samples. Hellinger distance for global bacterial (a) and fungal (b) assemblages, decomposed as weighted community diversity-abundance using tSNE. Processing batch type (batches with air samples only versus batches with air and soil samples) and sampling date (temporal variation) are visualised.

Fig. S18 | Taxonomic identity of reads removed during the decontamination process by location and habitat type. Taxonomic profile of putative contaminants removed from bacterial amplicon (a) and metagenome (c) data averaged by location. Taxonomic profile of putative contaminants removed from fungal amplicon (b) and metagenome (d) data averaged by location. NG air = near-ground air, HA air = high-altitude air. Relative abundance indicates occurrence as a percentage of all contaminant ASV and not the occurrence of legitimate sample ASV. Locations: 1, Canada; 2, Mongolia; 3, Spain; 4, Japan; 5, California, USA; 6, Kuwait; 7, Hilo, Hawaii, USA; 8, Mauna Kea, Hawaii, USA; 9, Singapore; 10, Coral Sea; 11, Namibia; 12, Chile; 13, South Africa; 14, Australia; 15, Uruguay; 16, New Zealand; 17, Southern Ocean; 18, Antarctica. Location metadata are shown in Supplementary Information.

Fig. S21 | Comparison of community clustering pre- and post-decontamination. Ordinations (tSNE based on Hellinger Distances) for bacteria raw data (a), bacteria post-decontamination pipeline (b); Fungi raw data (c) and fungi post-decontamination pipeline (d). We tested that our robust decontamination protocol did not have a significant impact on the strong ecological patterns by habitat type and location as highlighted in the manuscript (Fig. 2). We performed ordinations (tSNE based on Hellinger Distances) for the community separately for raw and filtered data. This was confirmed with strong and significant correlations for both Procrustes and Mantel tests based on Pearson's product-moment correlation for congruence for bacteria (Procrustes $m^2 = 0.089$, correlation = 0.955, $P = <0.01$ and confirmed by Mantel statistic $r = 0.744$, $P = <0.01$); and fungi (Procrustes $m^2 = 0.083$, correlation = 0.958, $P = <0.01$ and confirmed by Mantel statistic $r = 0.901$, $P = <0.01$).

Supplementary results

Fig. S22 | Global patterns in alpha diversity for bacteria and fungi in air and soil. **a)** DNA yield from air and soil samples, note that values are not directly comparable between soil and air. **b)** Bacterial alpha diversity metrics ($n = 529$). **c)** Fungal alpha diversity metrics ($n = 444$). Abbreviations: MK, Mauna Kea; NZ, New Zealand; SA, South Africa; SO, Southern Ocean; HA air, high-altitude air; NG air, near-ground air.

Fig. S23 | Comparison of diversity estimation using shotgun metagenomics and amplicon sequencing of air and soil. **a)** Relative abundance of twenty most abundant bacterial phyla estimated from metagenomes ($n = 120$). **b)** Relative abundance of twenty most abundant bacterial phyla estimated from amplicon sequencing ($n = 529$). **c)** Relative abundance of fungal phyla estimated from metagenomes ($n = 120$). **d)** Relative abundance of fungal phyla estimated from amplicon sequencing ($n = 444$). Community composition estimation using amplicon sequencing and shotgun metagenomics were positively correlated (Procrustes: Bacteria $m^2 = 0.76$, correlation = 0.49, $P = 0.001$; Fungi $m^2 = 0.56$, correlation = 0.66, $P = 0.001$), and so we focused our fine scale phylogenetic interrogation on amplicon sequence data because this approach allowed better ecological representation of the targeted assemblages in terms of sampling depth and taxonomic resolution. Locations: 1, Canada; 2, Mongolia; 3, Spain; 4, Japan; 5, California, USA; 6, Kuwait; 7, Hilo, Hawaii, USA; 8, Mauna Kea, Hawaii, USA; 9, Singapore; 10, Coral Sea; 11, Namibia; 12, Chile; 13, South Africa; 14, Australia; 15, Uruguay; 16, New Zealand; 17, Southern Ocean; 18, Antarctica. HA air, high-altitude air; NG air, near-ground air; NA, no taxonomy assigned.

Table S4 | The effect of habitat and location on structure of bacterial and fungal assemblages. Analysis was implemented using the R package manyglm for the top 5000 ASV (see Methods). P-values were calculated using 999 iterations via PIT-trap resampling. Res. Df = Error or Residual Degrees of Freedom, Df.diff = Difference in degrees of freedom, Dev = Deviance, Pr(>Dev) = P value. Both variables were significant in structuring bacterial and fungal assemblages.

Bacteria				
	Res.Df	Df.diff	Dev	Pr(>Dev)
(Intercept)	528			
Habitat	526	2	30431	0.001
Location	509	17	368576	0.001
Habitat:Location	492	25	47552	0.19

Fungi				
	Res.Df	Df.diff	Dev	Pr(>Dev)
(Intercept)	443			
Habitat	441	2	23811	0.001
Location	424	17	387268	0.001
Habitat:Location	407	25	47357	0.033

Fig. S24 | Dissimilarity of assemblages by habitat type and location. Jaccard Index for global bacterial (a) and fungal (b) assemblages, decomposed using PCoA. Clustering by habitat type (green, soil; blue, NG air; red, HA air) was also conserved when analysis was reiterated using only locations where concurrent sampling for all habitat types occurred to mitigate against potential sample-size effects.

Fig. S25 | Phylogenetic distance of assemblages by habitat type and location. Hellinger Distance for global bacterial (a) and fungal (b) ASV-defined assemblages, decomposed as weighted community diversity-abundance using tSNE. HA air, high-altitude air; NG air, near-ground air. Separation by location is evident except for a cluster of the regionally proximal New Zealand, Southern Ocean and Antarctic locations (Bacteria $n = 529$; Fungi $n = 444$). To ensure that classifications were appropriate to provide accurate ecological insight we also conducted a Procrustes analyses comparing PCoA with Hellinger distances between ASV and Genus defined communities. This found the observations to be highly congruent between the classification methods for bacteria ($m^2 = 0.239$, correlation = 0.872, $P = <0.01$) and fungi ($m^2 = 0.187$, correlation = 0.902, $P = <0.01$).

Fig. S26 | Global-scale distance decay plots for bacteria and fungi in air and soil. Shaded area surrounding line of best fit indicates 95% confidence intervals. HA air, high-altitude air; NG air, near-ground air. Significant linear distance decay relationships for diversity were observed for bacterial (Mantel test, Soil: $r = 0.357$, $P = 0.001$; NG air: $r = 0.353$, $P = 0.001$; HA air: $r = 0.433$, $P = 0.002$) and fungal (Mantel test, Soil: $r = 0.507$, $P = 0.001$; NG air: $r = 0.482$, $P = 0.001$; HA air: $r = 0.535$, $P = 0.004$) assemblages. The pattern for near-ground air was fairly pronounced compared to that for underlying soil and this reflects that soil habitats and their microbial diversity were markedly more diverse. Limited inference could be made for the pattern in high-altitude air due to lower sample numbers.

Fig. S27 | Null model networks for bacterial and fungal assemblages in air and soil. a) High-altitude air. **b)** Near-ground air. **c)** Soil. For nestedness estimates from phylum to family level all taxa were used, and for genus and ASV level the 1,000 most prevalent taxa. The null models were based upon statistical mechanics reconstruction of the taxa by location bipartite network. Maximum-likelihood was used to estimate the probability distribution that maximised the entropy function of the null network conditional on the constraint of the observed degree sequence, which was enforced as an average vector (Canonical ensemble).

Fig. S28 | Taxonomic composition of bacterial and fungal assemblages in air and underlying soil.

Estimates shown are for ASV-defined assemblages for a) bacteria ($n = 529$) and b) fungi ($n = 444$). Arrows indicate locations where aircraft sampling of high-altitude air was undertaken. A taxa filtering criteria of $<0.1\%$ mean relative abundance was used for these plots and so incomplete bars for some samples indicates taxa with very low abundance rather than unidentified taxa.

Fig. S29 | Co-occurrence of bacterial and fungal taxa in globally distributed air and soil. The scatterplots show number of ASVs (Y-axis) shared among $\geq$ number of samples (X-axis). Generally, fewer ASVs were shared across larger number of samples. Shared ASVs were determined by simple presence/absence of a given ASV between two assemblages (Bacteria, $n = 529$; Fungi $n = 444$).

Fig. S30 | Source contribution to observed diversity in air. a) Estimated contribution of aquatic, phyllosphere and soil sources to bacterial diversity. **b)** Estimated contribution of aquatic, phyllosphere and soil sources to fungal diversity. Location 3 (Spain) was impacted by a minor intrusion of Sahara Desert atmospheric dust during sampling. HA air, high-altitude air; NG air, near-ground air. Top row: green shading indicates source locations sampled in this study, grey boxes indicate data from other studies employed in the meta-analysis. Bottom and right: coloured boxes correspond with climate as shown in Fig. 3. Numbers in each box indicate the estimate proportion of contribution from a given source (top row) in each sink community (left).

Fig. S31 | Functional metagenomics profiling of targeted stress-response and metabolic genes by habitat type. Abundance values for selected genes of the included stress-response and metabolic pathways are expressed on the heatmap as copies per million reads. The illustrated values represent all samples (total $n = 120$) within each air and soil sample group. HA air, high-altitude air; NG air, near-ground air. Gene abundance data were expressed in terms of copies per million reads from HUMAnN, which takes into account library size differences between samples. For functional gene analysis, differentially more abundant genes in air versus soil were inversely correlated with biomass and taxonomic richness, they affiliated with taxa observed as enriched in air, and all values were averaged by location. We therefore interpreted the elevated abundance of genes in air as reflective of assemblage composition rather than an artefact of sampling effort.
