**Abstract:**

Numerous unwanted cells are removed from epithelial and endothelial tissues—in which cells are tightly connected to one another—without disturbing tissue integrity and homeostasis. Cell extrusion is a unique mode of cell removal from tissues, and it plays an important role in regulating cell numbers and the eliminating unwanted cells, such as apoptotic cells, cancer cells, and cells with a lower fitness in cell competition<sup>1-3</sup>. During this process, cells delaminate from the cell layer, to which they initially used to adhere, through communication with the neighboring cells<sup>4,5</sup>. Defects in cell extrusion are believed to associate with inflammation and cancer in epithelium as well as blood vessel dysfunction<sup>6,7</sup>. However, the correlation between them has not yet been evaluated owing to a lack of knowledge of the underlying mechanisms. In particular, the process whereby the cell exit from the tissue remains to be elucidated. Here, we report a novel and conserved execution mechanism of cell extrusion—common to mammalian cells and *Drosophila* epithelia—i.e., spatiotemporally regulated extracellular vesicle formation in extruding cells at a site opposite to the direction of extrusion. Particularly, we found that a lipid-scramblase-mediated local exposure of phosphatidylserine is responsible for extracellular vesicle formation and is crucial for the execution of cell extrusion, and inhibition of this process disrupted prompt cell delamination as well as tissue homeostasis. Furthermore, we revealed the mechanism underlying vesicle formation. Importantly, our results reveal that membrane dynamics is the driving force by a “rocket launch”-like mechanism behind the extrusion of cells from tissues, a fundamental cell behavior in multicellular organisms that is also observed in other contexts including cancer cell invasion and neural cell differentiation. Our understanding of this new mechanism of cell extrusion enables us to

**examine the relationship between cell extrusion abnormalities and the onset of various diseases.**

**Main Text:**

5           Although the contraction of the actomyosin complex produces the driving mechanical force for execution of cell extrusion <sup>8,9</sup>, how the cell delaminates from the tissue remains a fundamental yet unanswered question. We hypothesized that membrane dynamics play a key role in the execution of cell extrusion. To investigate this, first, we visualized the cell membrane with membrane-bound GFP (membrane GFP) and analyzed the detailed membrane dynamics in 10 both extruding cells and their neighboring cells. In Mardin-Darby canine kidney II (MDCKII) cell monolayers, cell extrusion occurs spontaneously after confluence to adjust cell density <sup>4</sup>. We found extensive budding of the membrane of extruding cells and the presence of many vesicles inside the neighboring cells via live-imaging analysis of membrane GFP-expressing MDCKII cells (92/92 extrusion events) (Fig. 1A and Movie S1). Immunostaining results revealed that 15 cleaved caspase3 is contained in the vesicles of the neighboring cells (110/113 extrusion events) in addition to the cytoplasm of extruding cells (Fig. 1B). This suggests that these vesicles are derived from extruding apoptotic cells and engulfed by their neighbors.

To verify this, we performed mosaic analysis via the co-culture of RFP-expressing and membrane GFP-expressing cells. The deformation process in extruding cells began with a slight 20 invagination of the apical surface, and after 15 min, the cells showed budding-like membrane dynamics (Fig. 1C and Fig. S1). Then, the budding was rapidly fragmented, and the shed fragments were engulfed by the neighboring cells, as shown by the GFP-positive vesicles containing RFP in GFP-expressing cells adjacent to RFP-expressing extruding cells (10/10

extrusion events) (Fig. 1D and Movie S2). Fragmentation and engulfment occurred transiently rather than continuously, and the remaining portion of the extruding cell after fragmentation delaminated from the cell layer to the apical direction (Fig. 1C and Fig. S1). Interestingly, fragmentation and engulfment occurred preferentially at the basolateral or basal parts of the extruding cells (10/10 extrusion events) (Fig. 1E and Movie S3). In addition, the protrusion of the extruding cell from the monolayer began simultaneously as fragmentation and engulfment (Fig. 1C and F). These results suggest that fragmentation and/or engulfment are involved in the execution of cell extrusion.

Apoptotic cells expose phosphatidylserine (PS) as an “eat-me” signal and are engulfed by phagocytes<sup>10</sup>. Staining results with Annexin V, a PS-binding protein, showed that extruding cells exposed PS, and signals were enriched at the basal and basolateral parts with a patched pattern (Fig. 1G), strongly suggesting that the cell fragments that exposed PS were then recognized and engulfed by the neighbors. LysoTracker staining results showed that the phagocytic vesicles fused with the lysosomes 30-60 min after the engulfment (Fig. S2).

To evaluate the function of engulfment during cell extrusion, we intended to disturb the engulfment process using the MFG-E8 mutant protein. Secreted MFG-E8 protein binds to both PS exposed on apoptotic cells and integrins on phagocytes to promote phagocytosis, whereas the MFG-E8-D89E mutant protein (D89E), which carries a mutation in the integrin-binding motif, inhibits PS-mediated phagocytosis in a dominant-negative manner<sup>11</sup>. Although we expected that D89E-overexpression in MDCKII cells prevents engulfment after fragmentation, we observed that it impaired the fragmentation process. Half of the cell extrusion did not show fragmentation, even after 25 min following the deformation of the cell shape (Fig. 2A, Fig. S3, and Movie S4). These extruding cells with delayed fragmentation despite the continuous membrane deformation

showed impaired protrusion from the cell layer and prolonged time to complete extrusion (Fig. 2B and C). Furthermore, upon D89E expression, some cleaved caspase3-positive cells were found in the cell layer without protrusion, indicating the impaired execution of cell extrusion (Fig. 2D). These results suggest that fragmentation and/or engulfment is critical for prompt cell extrusion.

Another mammalian epithelial cell line, EpH4, showed fragmentation during cell extrusion (61/61 extruding cells) at the basal half of extruding cells (7/7 extruding cells). However, the fragments were not rapidly engulfed by neighboring cells but remained in or were moved around the basolateral intercellular space (Fig. 2E and Movie S5). The masking of PS by the D89E mutant in EpH4 cells inhibited fragmentation and importantly, cell extrusion (Fig. 2F, G, H, Fig. S4, and Movie S6). The results from these two cell lines indicated that fragmentation, which is mediated by PS exposure, is a common process and promotes the protrusion of extruding cells. PS exposure in apoptotic cells is governed by the Xk-related protein (Xkr) scramblase family, particularly Xkr4, Xkr8, and Xkr9<sup>12</sup>. The knockdown of *Xkr8*, the most abundant among the three in EpH4 cells (Table S1), decreased PS exposure and caused abnormal fragmentation, impaired protrusion, and longer extrusion (Fig. 2I, J, K, and L), whereas the knockdown of *TMEM16F* (*Ano6*), the most abundant lipid scramblase belonging to the TMEM16 family in EpH4 cells (Table S1), did not affect fragmentation nor extrusion (Fig. S5).

Fragmentation was also observed in apoptotic cell extrusion induced by UV irradiation in cultured cells (Fig S6). To further show that fragmentation occurs *in vivo*, time-lapse imaging was performed on the pupal dorsal abdominal epidermis of *Drosophila*. During the early pupal stage, all large-sized larval epithelial cells (LECs) extrude in the basal direction, whereas small adult epithelial cells (histoblasts) replace the epithelial space through frequent cell division and

movement<sup>13,14</sup> (Fig. 3A). Upon extrusion of a lateral membrane-localized GFP (Lgl:GFP)-  
expressing LEC adjacent to other LECs, fragmentation of extruding cell was observed (23/23  
extruding cells) (Fig. 3A and Movie S7). In mosaic analysis in which RFP was expressed in  
LECs only whereas Lgl:GFP was expressed in both LECs and histoblasts (Fig. 3B), RFP-  
5 positive vesicles derived from extruding LECs were detected in the neighboring histoblasts (5 of  
5 extrusion events), indicating that fragmentation (and engulfment by the neighboring LECs and  
histoblasts) occurs during physiological cell extrusion *in vivo*. Fragmentation and engulfment  
were observed preferentially at the apical half of the extruding cells (4/5 extrusion events), which  
was in the opposite direction of extrusion (Fig. 3C). Apical fragmentation occurred after the  
10 apical surface, which was formerly occupied by extruding cells, was closed and covered by their  
neighbors (10/10 extrusion events) (Fig. 3D and Movie S8).

The ectopic expression of secreted Annexin V-EGFP fusion proteins (Annexin V:GFP) in  
histoblasts detected PS exposure in a speckled manner at the apical sites of extruding LECs,  
which are the likely sites to be fragmented, after the cell started to deform (13/13 extruding cells)  
15 (Fig. 3E, movie S9), whereas the expression of the mutant Annexin V:GFP (unable to bind to  
PS) did not (0/22 extruding cells). This result suggests that spatio-temporally regulated PS  
exposure triggers fragmentation. Annexin V:GFP-expression impaired both fragmentation and  
extrusion (data not shown) owing to the function to mask the exposed PS as reported in<sup>15</sup>.  
Furthermore, when Annexin V:GFP was expressed in LECs, the adult dorsal abdomen showed  
20 loss of continuity of the epidermis and bristles at the midline (Fig. 3F), a severe defect in cell  
death or extrusion as previously reported<sup>16</sup>. The knockdown of the *Drosophila Xk* gene (*Xk* or  
CG32579), a single homolog of the mammalian Xkr family, showed abnormality in the  
fragmentation of extruding cells (Fig. 3G, Fig. S7). The progression of cell extrusion after the

closure of the apical surface of the extruding cells was impaired in the *Xk*-knockdown epidermis as evidenced by the persistence of extruding cells in the cell layer for an extended time (Fig. 3H). The replacement of larval cells by histoblasts was delayed in the *Xk*-knockdown pupal epidermis (Fig. 3I).

5            In another physiological cell extrusion, during cell turnover in the adult intestinal epithelium, fragmentation and engulfment occurred in the *Drosophila* midgut as indicated by the formation of some vesicles in the neighboring cells (Fig. S8), as well as in the mouse intestinal organoid as shown by time-lapse imaging results (Fig. S9 and Movie S10). When *Xk* was knocked down in an enterocyte-specific manner in the *Drosophila* midgut, an increased tissue  
10 width and shorter lifespan were observed (Fig. S10). These results indicate that PS exposure-induced fragmentation of the extruding cells is a universal process that plays a significant role in the execution of cell extrusion to ensure tissue development and homeostasis.

            Lastly, we speculated that fragmentation involves the local formation and release of extracellular vesicles (EVs), which are observed in blood coagulation, intercellular signal  
15 transduction, and various pathological processes<sup>17-19</sup>. The size of fragments formed during cell extrusion ranges between 0.5 and > 2  $\mu\text{m}$  in diameter, and a small part of them were positive for DNA staining (a positive example: Fig. S11 and a negative example: Fig. 1B). In EVs, including exosomes, microvesicles, and apoptotic bodies, PS exposure and actomyosin accumulation at the budding sites, mediated by the function of the Arf family, Phospholipase D (PLD), and  
20 extracellular regulated kinase (ERK), have been reported in microvesicle formation<sup>20,21</sup>. In addition to the requirement of PS exposure for the fragmentation (Fig. 2 and 3), actin or myosin accumulated around the root of the budding sites of the fragments in MDCKII cells and *Drosophila* LECs (Fig. 4A and B).

When *Arf6*, *Arf1*, or *Pld1* was knocked down in EpH4 cells, impaired fragmentation and delayed extrusion with defective protrusion were observed (Fig. 4C–E, Fig S12). Extruding EpH4 cells with *Arf6* or *Pld1*-knockdown showed local PS exposure (control; 77%, *Arf6*-knockdown; 55%, and *Pld1*-knockdown; 58% of extruding cells), consistent with that the PS exposure precedes EV formation. Arf51F (homologous to mammalian Arf6) accumulated at the apical part of extruding cells in *Drosophila* pupa during fragmentation (6/6 extrusion events) (Fig.4F). *Arf51F*-knockdown in the pupal epidermis showed impaired fragmentation and delayed progression of cell extrusion (Fig. 4G and H). Furthermore, the knockdown of *Arf79F* (homologous to mammalian *Arf1*), which is more abundant than *Arf51F*, in the *Drosophila* midgut (Table S1) in an enterocyte-specific manner resulted in enlarged midguts and shorter lifespans (Fig. S13). These data indicate that the fragmentation of the extruding cells is spatio-temporally restricted EV formation governed by a similar mechanism as microvesicle formation and promotes cell protrusion, thus the execution of cell extrusion.

Taken together, our findings reveal that local PS exposure and subsequent EV formation mediated by PLD and the ARF family in extruding cells is a conserved mechanism that promotes efficient cell extrusion. Prolonging this process caused defects in epithelial tissue, suggesting that prompt execution of extrusion is critical for tissue homeostasis including such as its barrier function. EV formation occurs at the site opposite the direction of extrusion in the apico–basal axis and simultaneously with cell protrusion. Thus, membrane dynamics in extruding cells produce a kind of driving force of extrusion, in addition to the actomyosin complex formed by the neighboring cells and/or extruding cells <sup>8,9</sup>, and might control the directionality of extrusion. The polarized formation and/or release of the vesicles may produce force for cell protrusion by touching the neighboring cell membrane or the extracellular matrix similar to the propulsion of

rockets (Fig. 4I). Alternatively, vesicle release might contribute to the promotion of the invasion of neighboring cells by opening the space, thus facilitating cell extrusion. Promoting cell extrusion is a novel physiological function of EVs and PS exposure. Whether the released vesicles function in signal transduction via this engulfment, as in other contexts<sup>22</sup>, has to be investigated. Future studies on EV formation in extruding cells will provide new insights into EV biology and increase the understanding of the relationship between impaired cell extrusion and epithelial diseases, including cancer and inflammation.
