Version of Record: A version of this preprint was published at Journal of Cancer Research and Clinical Oncology on July 8th, 2021. See the published version at <https://doi.org/10.1007/s00432-021-03692-6>.

Abstract

Purpose: Regardless of professional societies agreed that CT screening inconsistent with recommendation leads to radiation-related cancer and unexpected cost, many patients undergo unnecessary chest CT before treatment. The goal of this study was to assess the overuse of Chest CT in different type of patients.

Methods: Data on 1853 patients who underwent pulmonary resection from May 2019 to May 2020 were retrospectively analyzed. Data collected include age, sex, follow-up time, density and size of nodules and frequency of undergoing Chest CT. Pearson χ^2 test and logistic regression were conducted to compare the receipt of CT screening.

Results: Among 1853 patients in the study, 689 (37.2%) had overused Chest CT during follow-up of the lung cancer. This rate was 16.2% among patients with solid nodules, 57.5% among patients with pure ground glass opacity (pGGO), and 41.4% among patients with mixed ground glass opacity (mGGO) ($P < .001$). 50.7% in the "age ≤ 40 " group, 39.8% in the "41 \leq age ≤ 50 " group, 38.7% in the "51 \leq age ≤ 60 " group, 32.3% in the "61 \leq age ≤ 70 " group, 27.8% in the ">70" group underwent unnecessary CT ($P < .001$). Female get more unnecessary CT than male (40.6% vs 32.8%, $P < .001$). Factors associated with a greater likelihood of Chest CT is the density of nodules (odds ratios [ORs] of 0.53 for mGGO; 0.15 for solid nodule, $P < .0001$, vs patients with pGGO).

Conclusion: roughly 37% patients with pulmonary nodules received Chest CT too frequently despite national recommendations against the practice. Closer adherence to clinical guidelines is likely to result in more cost-effective care.

Introduction

Lung cancer is the leading cause of cancer death worldwide, with an estimated 1.6 million deaths annually.¹ Since a high range of lung cancer occurs and develops without any symptom until end-stage, screening becomes significant method of spotting lung cancer. As the US National Lung Screening Trial (NLST), Netherlands–Leuven Longkanker Screenings Onderzoek (NELSON) and other trial revealed that Computed Tomography (CT) can produce more effect compared with X-ray, Chest CT becomes the first choice of lung cancer screening.²⁻⁵

However, CT is not a perfect choice for lung cancer screening. According to John Brodersen, 49% of detected cancers by Low-dose CT (LDCT) may be overdiagnosed,⁶⁻⁷ and researchers also mentioned that risk of radiation-induced cancers can be a potentially harmful effect of Chest CT which is cumulative over a lifetime.^{2,8-11} Another concern is the cost-effectiveness of the Chest CT. The NLST results suggested that screening with low-dose CT cost \$100,000 per QALY gained, but study of William C. Black showed that screening conducted outside the trial may be costlier if patients' counseling and follow-up are

properly accounted for the price.^{2,12} The cost could become more considerable if the number of unnecessary CT scans increase, making a heavy burden for patients and economy of healthcare.

To minimize the risk of radiation and unnecessary cost, multiple specialty societies have issued recommendations against Chest CT for patients with suspicious pulmonary nodules.¹³⁻¹⁵ Although specific recommendations differ somewhat, all societies agreed that CT screening is not an examination which can be experienced without limitation. But even with these numerous guidelines and recommendations, overuse of Chest CT is routinely performed in patients with nodule suspicious for pulmonary tumor. The goal of this study was to assess the use of Chest CT in patients with pulmonary nodules, and identify the demographic and clinical factors associated with receipt of Chest CT.

Materials And Methods

Patients and samples

From May 2019 to May 2020, we consecutively procured data of lung cancer patients who underwent pulmonary resection in the Department of Thoracic Surgery, Fudan University Shanghai Cancer Center, Shanghai, China. The frequency of CT screening is collected by telephone follow-up and checking medical history. Subjects eligible for this study had to meet the following criteria: complete follow-up history and clinical data. Patients who received neoadjuvant chemotherapy were excluded from the study because of inconsistencies of the reason they get Chest CT. Patients with a recurrent lung cancer, with multiple concurrent cancers, and with former other malignancies were also excluded from the study. Patients who underwent Chest CT because of symptoms related to lung cancer were excluded since the NCCN guideline cannot apply to them. This research was approved by the Institutional Review Board of the Fudan University Shanghai Cancer Center, Shanghai, China. Written informed consent was obtained from all patients.

As different patients need different strategies of CT screening, we used the guideline of NCCN which gave the advice for patients who incidentally found nodules suspicious for lung cancer,¹³ and then grouped them into two groups: abiding by the guideline or not.

Statistical Analysis

All the statistical analyses were performed in the SPSS for Windows (Version 16.0, Chicago, IL). We assessed the baseline characteristics of patients included in our sample, grouped them by following the guideline or not. Age, sex, density and size of nodules are modeled as categorical variables. Variables were reported as counts and percentages, and groups were compared using chi-square tests for significance. We used the Pearson χ^2 test to compare the lung cancer detection rate. Finally, we performed a multivariable logistic regression for the likelihood of overusing Chest CT for staging. P-values were two-tailed for all the tests. Statistical significance was set as $p < 0.05$.

Results

Among 2667 patients with nodules suspicious for lung cancer, a total of 1853 patients met inclusion criteria (Figure 1). All patients were Chinese. Baseline demographic and clinical characteristics of the cohort are summarized in Table 1.

Table.1 Baseline Demographic and Clinical Characteristics				
variable	Overall Cohort n (%)	Not abiding by the guideline n (%)	abiding by the guideline n (%)	P value*

Overall, during the 12-months study period, around 37.2% of our patients underwent excessive CT. The proportion of females was 56.0%. 40.6% of them ignored the recommendation, while this rate changed to 32.8% among males. The percentage of patients ≤40 years, 41 to 50 years, 51 to 60 years, 61 to 70 years

and >70 years were 11.3%, 17.5%, 30.3%, 30.9% and 10.1%, and 50.7%, 39.8%, 38.7%, 32.3%, 27.8% of them received unnecessary examination.

As for density of nodules, 25.8% found pure ground glass opacity (pGGO), 40.9% found mixed ground glass opacity (mGGO), and 32.2% found solid nodules during their screening. 57.5%, 41.4%, and 16.2% of them did not abide by the guideline of NCCN.

Since different density of nodules need different screening strategies, we grouped patients by their density of nodules and assessed how many patients who need different follow-up time were inconsistent with NCCN (Table 2). As a result, for patients with pGGO, 55.7% of patients who need 0 follow-up violated the recommendation, and this rate ranged into 51.4%, 81.3%, 90.9%, 88.9% for who need 1, 2, 3 and more than 3 follow-ups. As for patients with mGGO, 50.9%, 24.1%, 59.0%, 40.8%, 46.2% patients who need 0, 1, 2, 3 and more than 3 follow-ups were not adhere to the guideline, and 11.2%, 11.8%, 34.4% patients with solid nodules who need 0, 1, 2 follow-ups underwent unnecessary Chest CT for screening.

In univariable analysis, factors associated with greater use of CT included younger age (odds ratios [ORs] of 0.64 for 41–50 years, $P=.014$; 0.62 for 51–60 years, $P=.003$; 0.47 for 61–70 years, $P<.001$; and 0.37 for ≥ 71 years, $P<.0001$; vs ≤ 40 years), female sex (OR, 1.40; $P<.001$) and lower nodule density (ORs of 0.52 for mGGO, $P<.001$; 0.14 for solid nodule, $P<.001$) (Table 3). In terms of the following-up time, patients tended to abide by the guideline when the first follow-up was recommended (ORs of 0.84 for patients with pure GGO, $P=.040$; 0.30 for mGGO, $P<.001$).

Correlations among patients' unnecessary CT scan with clinical features were further evaluated by multivariable analysis using logistic regression analysis (Table 4). The result suggested that density of the nodules were independent predictors of overusing Chest CT (ORs of 0.53 for mGGO, $P<.0001$; 0.15 for solid nodule, $P<.0001$, vs patients with pGGO).

Discussion

Despite the mention of risk about overuse of Chest CT by specialty societies, patients were still willing to get the examination as many as possible. In this retrospective cohort study, we found that almost 1 in 3 patients received unnecessary lung cancer screening, and the rate dramatically varied by different characteristics. Previous study suggested the disadvantage of unnecessary Chest CT, and there were studies about overuse of Chest CT in patients with breast cancer or studies about lung cancer screening inconsistent with USPSTF,¹⁶⁻¹⁸ but to our knowledge, this is the first study to assess the overuse of Chest CT during follow-up after finding nodules suspicious for lung cancer.

Our study finally showed that overuse of CT is likely to happen in patients with less density, and patients with pGGO most tend to undergo CT scan which is inconsistent with recommendation. As a fact, there is no perfect method to distinguish malignant and benign GGO with accurate certainty. A period of follow-up may be helpful for diagnosis, but the interval of follow-up can be longer than 1 year. Lee et al reported that pure GGO lesions ≤ 10 mm have a volume-doubling time of more than 400 days, and a study from Japan also suggested that the optimal observation period for patients with multiple GGOs is 36 months.¹⁹⁻²⁰ NCCN guidelines recommended that both pGGO and mGGO < 6 mm do not require any follow up and that pure GGOs ≥ 6 mm should be followed every 2 years, for up to 5 years.¹³

But since a percentage of GGNs disappear spontaneously in short term,²¹ some medical workers routinely ask patients to get examination again in 3 months after they found pulmonary opacities to check if the GGO is only an inflammation, leading to a potential risk of overusing CT scan. Another study of Lee et al suggested that 2 of 90 GGNs (2.2%) followed up for more than 4 years showed significant growth after 4 years, and whether patients need Chest CT after 5 years follow-up still remains a problem.²² These can be reasons for undergoing Chest CT without complying with the recommendation.

Female and younger patients also showed higher rate of inconsistency with NCCN, but this factor may not be the true influencer of unnecessary Chest CT as percentage of GGO is also higher among these groups in our study. 30.8% of females found pGGO during their Chest CT screening, whereas only 14.8% of males found pGGO nodules. This result is in line with those reported by Huang et al.²³ Their study revealed that pGGO is associated with females, and although there is not significance difference, younger age patients get more pGGO in the research.

Given that our analysis relied on data of Fudan University Shanghai Cancer Center and telephone following-up, there are some incumbent limitations to consider. Prior studies have already revealed significant geographic variation about screening and therapy protocol in clinical practice.²⁴⁻²⁵ A certain level of recalling bias should be acknowledged, and furthermore, our conclusions only apply to the population analyzed – patients who got pulmonary resection in Fudan University Shanghai Cancer Center. We also excluded patients who had history of other malignant tumors or neoadjuvant therapy, which can lead to selection bias. These patients usually have more advanced disease, and were more likely to get examination for accurate diagnosis, but the purpose of CT for them could be evaluating the therapeutic effect instead of screening, so their examination history shouldn't be judged by the guideline.

It would be interest to evaluate the variations among different area and hospitals, and further research in this aspect is warranted.

Conclusion

This retrospective analysis of the data suggests overuse of unnecessary Chest CT in patients with lung nodules suspicious for lung cancer, and this rate vary by radiologic density of the nodules. This dissimilarity may stem from clinical uncertainty, general lack of familiarity with national recommendations and patients' anxious about tumor. Efforts to disseminate evidence-based best practices and adherence to the guidelines will not only spare patients' unnecessary radiation, also curb excessive spending.
