Abstract

Iron deposition in various organs can cause endocrine complications in patients with transfusion-dependent beta-thalassemia. The aim was to investigate the relationship between endocrine complications and pancreatic iron overload using magnetic resonance imaging (MRI). Forty patients with transfusion-dependent thalassemia (TDT) were enrolled in the study. The magnetic resonance imagings of the patients were performed using a 1.5 Tesla Philips MRI scanner. Two out of three patients had at least one clinical endocrine complication. The rate of iron deposition was 62.5% in liver, and 45% in pancreas tissue, and was 12.5% in heart tissue. Pancreatic T2* and hepatic T2* values were significantly positively correlated ($p = 0.006$). Pancreatic T2* and ferritin were significantly negatively correlated ($p = 0.03$). Cardiac T2* values were negatively correlated with fasting blood glucose ($p = 0.03$). Patients with short stature had significantly higher cardiac iron burden (22.3 vs. 36.6 T2*ms; $p < 0.01$) and patients with hypothyroidism had higher liver iron concentrations (9.9 vs. 6.4 LIC mg/g; $p = 0.05$). The ferritin level of 841 ng/mL, and liver iron concentration (LIC) value of 8.7 mg/g were detected as the threshold level for severe pancreatic iron burden (AUC 70%, $p = 0.04$, AUC 80%, $p = 0.002$, respectively). Moreover, males were found to have decreased pancreas T2* values compared with the values in females (T2* 19.3 vs. 29.9, $p = 0.05$). Patients with higher ferritin levels over than 840 ng/mL should be closely monitored for pancreatic iron deposition, and patients with endocrine complications should be assessed in terms of cardiac iron burden.

Introduction

Transfusion-dependent thalassemia (TDT) requires regular blood transfusions, and the iron overload is unavoidable if chelation therapy is not suitable [1]. Iron burden in liver, heart, pancreas, and hypophysis can originate a complication spectrum.

Diabetes, hypogonadism, short stature, and osteoporosis were the commonly detected endocrine disorders among patients with thalassemia [2]. Awareness of complications, early monitoring of patients, and starting the necessary chelator may decrease the rate of endocrine comorbidities [3].

Iron can also deposit in extrahepatic organs such as heart and pancreas specifically in the form of non-transferrin-bound iron (NTBI) [4]. Therefore, these organs are also sensitive to chelation therapy [5]. Screening the association of iron burden in extrahepatic organs is one another way of evaluation for patients. Studies supporting these assumptions showed that iron overload in endocrine organs can have association with hepatic and cardiac functions [6, 7].

Therefore, the close follow-up of patients in terms of iron burden in extrahepatic organs (e.g. heart, pancreas) with magnetic resonance imaging (MRI) is important for the physicians. In the present study, we aimed to screen the endocrine comorbidities of TDT patients, and to investigate the relationship between comorbidities and iron overload in pancreas, liver, and heart.

Materials And Methods

Study Design

This research was a cross-sectional study, which was conducted in Thalassemia Center of Istanbul Faculty of Medicine in Turkey. The transfusion dependent thalassemia patients who were routinely followed up in our center were asked to participate in the study. Volunteer participants underwent MR imaging between January 2018, and April 2018 in Radiology Department of Istanbul Faculty of Medicine.

Participants

Forty patients (females 50%) with TDT who had received regular transfusion (14 thalassemia intermedia, and 26 thalassemia major patients) were recruited in the study. Patients accepted to have MRI scans of the pancreas during routine scanning of the heart and liver.

All patients had received blood transfusion in every 3 to 4 weeks (the median transfusion number was 18 per year) to maintain the hemoglobin level between 9–10 g/dL. Forty percent of the patients' parents had consanguineous marriage.

Thirty (75%) patients had received deferasirox (DFX), nine patients (23%) had received deferiprone (DFP), and one patient used both DFP, and deferasirox. No problem was detected in adherence to chelation therapy. (Table 1).

Table 1
Clinical and laboratory characteristics of the patients

Characteristics	Transfusion Dependent Thalassemia (n = 40)
Gender (f)	20 (50%)
Age mean ± SD years	32.1 ± 10.6
Disease duration mean ± SD years (median)	30.3 ± 10.5 (30)
Age of diagnosis mean ± SD months (median)	22.5 ± 26.3 (12)
Age of starting regular transfusion mean ± SD months (median)	31.0 ± 37.4 (12)
Age of starting iron chelation mean ± SD months (median)	107.9 ± 90.0 (84)
Age of splenectomy mean ± SD months (median)	181.6 ± 90.7 (168)
Transfusion number annually mean ± SD (median)	18.1 ± 3.9 (18)
Body mass index mean ± SD kg/m ²	22.0 ± 3.1
Splenectomy (yes)	25 (62%)

Characteristics	Transfusion Dependent Thalassemia (n = 40)
Chelation Therapy	30 (75%)
DFX	9 (23%)
DFP	1 (2%)
DFX + DFP	
Endocrine Complications	20(50%)
Osteoporosis	12 (30%)
Hypogonadism	9 (22%)
Diabetes	8 (20%)
Hypothyroidism	6 (15%)
Short stature	

Table 2
The findings of MRI investigations of the patients

Characteristics	Parameters
Ferritin	1336.8 ± 1039.1
mean ± SD ng/mL	(987)
(median)	21 (52%)
< 1000 ng/ml	12 (30%)
1000–2000 ng/ml	7 (18%)
> 2000 ng/ml	
Pancreas R2*	121.7 ± 168.1
mean ± SD Hz	(41.6)
(median)	22 (55%)
< 48 Hz	6 (15%)
48–100 Hz	3 (7.5%)
100–150 Hz	9 (22.5%)
> 150 Hz	
Pancreas T2*	24.6 ± 17.4
mean ± SD ms	(24)
(median)	18 (45%)
< 21 ms	22 (55%)
> 21 ms	
Cardiac T2*	34.4 ± 13.4
mean ± SD ms	(36.8)
(median)	4 (10%)
< 10 ms	1 (2.5%)
10–20 ms	35 (87.5%)
> 20 ms	

Characteristics	Parameters
Hepatic T2*	6.2 ± 6.3
mean ± SD ms	(3.1)
(median)	4 (10%)
< 1.4 ms	21 (52.5%)
1.4–6.7 ms	15 (37.5%)

mean ± SD mg/g	(6.9)
(median)	

Table 3
Hepatic and cardiac iron burden of patients with pancreatic iron overload

Pancreas R2* level	Hepatic Iron Burden	Cardiac Iron Burden
> 40 Hz	76%	19%
> 50 Hz	88%	24%
> 60 Hz	88%	25%
> 70 Hz	88%	29%
> 80 Hz	92%	33%
> 90 Hz	92%	33%
> 100 Hz	92%	33%
Among patients with pancreatic R2*>80 Hz, 92% of patients had hepatic iron overload and 33% of patients had cardiac iron overload		

Cardiac iron overload was accepted as T2* value < 20 ms [8], hepatic iron overload was accepted as T2* <6.7 ms [9], and pancreas iron overload was accepted as T2* <21 ms or R2* > 48 Hz [10, 13], some other studies accepted T2* level as 26 ms [11, 12] - Pancreas R2* more than 150 Hz was accepted as moderate to severe pancreatic iron overload [6].

Magnetic Resonance Imaging

In this study, unenhanced upper abdomen MRI images were obtained using a Philips Achieva 1.5Tesla system (Achieva 1.5T A-series, Philips, Holland). The images were taken in supine position as the patients hold their breath.

The imaging protocol consisted of the following sequences as coronal plane spectral attenuated inversion recovery (SPAIR), coronal plane T2W Turbo Spin Echo (TSE), axial plane T2W–TSE, and merged fast field echo (M-FFE), and dual fast field echo (DUAL-FFE) the sequence we use for the actual iron calculation. Philips M-FFE is a T2 * weighted gradient echo sequence in which transverse magnetization is spoiled with long repetition time (TR). Gradient echoes obtained in different TE values in the M-FFE sequence are combined in a single image with a reconstruction algorithm.

The sections to be measured were obtained from the mid-hepatic level, the section where the vascular structures were not intensely monitored so that the liver was not affected by vascular flow artifacts. In the calculating program we used, the values obtained were averaged by placing three ROIs at the level determined in the liver and pancreas as iron accumulation within the hepatic lobule and pancreas may not be homogeneous. To detect pancreatic iron, the sections where pancreas could be best evaluated were selected, and studied in the iron analysis program using the Wood method. The Wood method runs 16 T2*-weighted single-echo gradient echo sequences in a single-breath-hold with constant flip angle (20°), constant TR (400 ms), and increasing TE (range 8–19, delta-TE 0.8 ms), field-of-view 400 mm. The R2* was measured by inserting the observed data to a mono-exponential model with offset to develop a parametric map [14]. In the study, the Wood method was used to calculate the iron accumulation in the liver, and pancreas. T2* is the gradient echo equivalent of T2 in spin echo. The R2* value is the reciprocal of the T2* value ($R2^* = 1000 / T2^*$).

Additionally in dual echo chemical shift imaging in 1.5 T MRI, the signals are collected in the same TR interval as 2.3 and 4.6 ms and their multiples at two different echo times (short echo / out of phase, long echo / in phase). When the transverse magnetic vectors of the fat and water protons in the same voxel are in the same direction (in phase) additive (water + fat) signal and 180 degrees in the opposite direction (out of phase) decreasing (water – fat) signal is obtained. This method enables visual and quantitative measurement of steatosis. When measuring from the liver in patients with heterogeneously distributed hepatosteatois, ROI was placed in areas where steatosis is not present by visual evaluation with the help of dual echo sequences.

However, it should be noted that hepatic fibrosis and inflammation may decrease the T2 shortening effect caused by iron by prolonging the T2 relaxation time. But, a similar limitation occurs in T2 relaxometry mapping, which is another measurement method because fibrosis prevents diffusion (14). Since fat is a complex molecule, the presence of steatosis accelerates T2 dephasing and affects T2 * measurement. The Wood method we used in our study is a limitation of our study, since it is not a method that simultaneously performs spectral fat sampling while measuring T2 (14).

Especially, considering that MRI examination is more competent in detecting moderate to severe fat (38), we have reduced this limitation by not including patients with visually evident hepatosteatois in dual echo chemical shift examination.

Endocrinologic evaluation

Patients diagnosed as having endocrinologic complications were followed up in the endocrinology outpatient clinic, and the diagnosis was established in accordance with the clinical guidelines [15].

Diabetes mellitus was described as the fasting glucose over 126 mg/dL confirmed by repeated tests (at least two occasions) or any time blood sugar detected over 200 mg/dL. Hypothyroidism was considered as the lack of free thyroxin (fT4) with high (primary) or low-to-normal thyroid-stimulating hormone (TSH) (secondary). Osteoporosis was considered with decreased bone mineral density (T score below -2.5 SD or Z score below -2 SD), and fracture history. Hypogonadism was defined as the lack of secondary sex characters at age 13 years in girls and 14 years in boys. For gonadal development, laboratory confirmations were performed by an endocrinologist. Short stature was described as height measurement below -2 SD.

Data analysis

The Statistical Package for the Social Sciences (SPSS) 22 software was used in the statistical analyses. Student's t-test, the Mann-Whitney U test, correlation analysis, and receiver operating characteristics (ROC) curve analysis were used. $p < 0.05$ was considered as significant.

Ethical approval

The study was approved by the Ethics Board of the Istanbul University (protocol no: 201821).

Results

The mean disease duration was 30.3 ± 10.5 years, and mean age at diagnosis was 22.5 ± 26.3 (median 12) months. The mean age of starting regular transfusion was 31.0 ± 37.4 (median 12) months, and the mean age of starting iron chelation was 107.9 ± 90.0 (median 84) months. The mean age of splenectomy was 181.6 ± 90.7 (median 168) months. Twenty-five (62%) patients had undergone splenectomy. The median body mass index was 21 kg/m^2 . The median age of first menstrual cycle was 16.5 years for girls.

One or more clinical endocrine complications were detected in 65% of the participants ($n = 26$). The frequency of complications was 50% for osteoporosis ($n = 20$), 30% for hypogonadism ($n = 12$), 22% for diabetes mellitus ($n = 9$), 20% for primary hypothyroidism ($n = 8$), and 15% for short stature ($n = 6$) (Table 1).

The mean serum ferritin level was $1336.8 \pm 1039.1 \text{ ng/mL}$ (median 987). The serum ferritin level was detected lower than 1000 ng/mL in half of the patients. Ferritin levels were slightly higher in males (1405 vs. 1268 ng/mL , $p = 0.68$) compared with the levels in females.

The pancreas MRI showed the mean $R2^*$ value as 121.7 ± 168.1 (median 41.6) Hz, and the mean $T2^*$ value as 24.6 ± 17.4 (median 24.0) ms (Table 2). Eighteen patients (45%) had iron overload in the pancreas, and nine (22.5%) patients had moderate to severe pancreas iron burden ($R2^* >150$ Hz). Above the pancreatic $R2^*$ level of 80 Hz, the percentage of patients with hepatic and cardiac iron overload reached a plateau (Table 3). Patients with endocrine complications had nonsignificantly lower mean

pancreas T2* values compared to the values in patients with no endocrine complications (21.9 vs. 29.6 ms, $p = 0.18$). The mean pancreas T2* values of patients with diabetes was insignificant compared with the values in patients without diabetes (21.8 vs. 25.4, $p = 0.59$). No significant correlations were detected between pancreatic MR values with fructosamine, fasting blood glucose, insulin, C-peptides, and HOMA-IR indexes ($p > 0.05$).

Ferritin level was positively correlated with pancreas R2* ($r = 0.42$, $p = 0.006$) and negatively correlated with pancreas T2* ($r = -0.33$, $p = 0.03$), and hepatic T2* value ($r = -0.35$, $p = 0.02$). The pancreas T2* value was positively correlated with hepatic T2* ($r = 0.42$, $p = 0.006$) and negatively correlated with liver iron concentration ($r = -0.37$, $p = 0.01$). The pancreatic T2* value was significantly lower in males (19.3 vs. 29.9, $p = 0.05$), however, the rate of pancreatic iron overload showed no difference in accordance with sex ($p = 0.52$). However, ferritin, and hepatic and cardiac T2* values did not differ by sex.

The cardiac T2* value was negatively correlated with fasting blood glucose ($r = -0.33$, $p = 0.03$). Ferritin level was positively correlated with fasting blood glucose ($r = 0.37$, $p = 0.02$) and HOMA-IR ($r = 0.32$, $p = 0.04$).

Patients with short stature had significantly lower cardiac T2* (22.3 vs. 36.6 ms, $p = 0.01$) values. Patients with hypothyroidism had higher liver iron concentrations (9.9 vs. 6.4 LIC mg/g; $p = 0.05$). Fifty five percent of the patients ($n = 18$) had no pancreatic iron overload (i.e. pancreatic T2* >21 ms), 87.5% of the patients ($n = 35$) had no cardiac iron burden (i.e. cardiac T2* >20 ms), and 37.5% of the patients ($n = 15$) were free of hepatic iron burden (i.e. hepatic T2* >6.7 ms) (Fig. 1).

The serum ferritin level of 841 ng/mL was detected as the threshold level for liver iron deposition with 80% sensitivity and 80% specificity ($p = 0.002$, AUC = 0.80) and was determined as the threshold level for severe pancreatic iron burden with 83% sensitivity and 54% specificity ($p = 0.04$, AUC = 0.70). Above the ferritin level of 841 ng/mL, the risk of severe pancreatic iron overload increased 5.7-fold [odds ratio (OR) 5.7; 95% CI: 1.06–31.27]. The value of 8.7 mg/g for LIC was detected as the threshold level for severe pancreatic iron deposition (83% sensitivity and 78% specificity; $p = 0.002$, AUC = 0.80). Above the LIC level of 8.7 mg/g, the risk of severe pancreatic iron overload increased 12.5-fold (OR 12.5; 95% CI: 2.22–70.18).

No significant correlation was found between pancreas iron deposition, with chelation type, and age.

Discussion

In this study, we showed that at least one clinical endocrine complication was detected in two out of three TDT patients. The rate of iron deposition was 62.5% in liver, and 45% in pancreas tissue, and was 12.5% in heart tissue. The serum ferritin level of 841 ng/mL was shown as a threshold of iron deposition for liver, and for severe pancreatic iron burden. The pancreatic R2* value of 80 Hz was regarded as the threshold level for further cardiac and hepatic iron evaluation. Patients with short stature showed more

iron load in the heart, and the more iron in heart resulted with the higher fasting blood glucose in serum. This result may suggest that patients with iron burden in the heart are at risk for diabetes.

As chelation therapy increased the life span of thalassemia patients, previously unminded complications foremost the endocrinal complications gained importance (16–20). The hypothetical reality of these complications is based on severe iron burden in endocrine organs, which disturbs their synthesis function. From the clinical practice point of view, the unfavorable effect of ferritin on pubertal development can be minimized by the use of appropriate chelation therapy in proper time [21, 22]. A very recent study showed the good effect of appropriate chelation therapy on endocrinologic complications in children with thalassemia [23].

We found that almost half of the patients had pancreatic iron overload. Noetzli et al. [6] and Au et al. [10] found the pancreatic iron load as 80%, Kolnagou et al. [24] found as 85%, de Assis et al. [13] found as 86%, and Meloni et al. [12] found a rate of 93% in patients with thalassemia. Our finding of a more favorable rate is debatable because half of the patients had a higher serum ferritin level over 1000 ng/mL. Even if we had chosen the cut-off value as T2* 26 ms, the iron overload rate in pancreas would be 50%. Furthermore, thalassemia major population and the T2* methodology might be the other possible explanations as it is dependent to the sequence, the software analysis, and the single scanner. On the other hand, our patients were closely followed up using proper chelation therapy.

One of the clinical benefits of MR imaging is that it is more accurate than serum analysis of ferritin in these patients. Previously, a serum ferritin level of over 2500 ng/mL was accepted as a risk factor for mortality in patients with thalassemia [7], currently, a serum ferritin level of 841 ng/mL was detected as the threshold level for liver iron burden and severe pancreatic iron burden using MR imaging. Moreover, a pancreatic R2* value of 80 Hz should alert us to cardiac and hepatic iron evaluation. Similar value of R2* (100 Hz) was shown by Noetzli et al. [6]. The relationship between MR results of organs can clearly show the systemic iron burden, and inform about the following complications that will occur.

Males were found to have a decreased T2* value in the pancreas in the present study. Moreover, we found a decreased level of insulin, and increased level of fructosamine in males compared with the levels in females ($p = 0.06$ and $p = 0.05$, respectively). We found no supporting data in the literature. No sex difference was detected between the diabetic patients. Disease duration, age and body mass index showed no difference between male and females. We found no helpful cause for this discrepancy. Pancreatic iron overload causes decreased insulin secretion and thus precipitating diabetes in patients with thalassemia. Insulin resistance, and insulin deficiency together revealed the complexity of diabetes in thalassemia [25, 26]. Thus, pancreatic and liver iron overload is shown to be associated with diabetes in patients with thalassemia [27]. Seventy percent of male patients had hepatic iron overload while 55% of female patients had hepatic iron burden. This finding illustrates that male patients with TDT should be closely followed up in terms of diabetes.

Using MR imaging, recent studies revealed the association between heart and liver with other organs in terms of iron overload [28–30]. We showed that the rate of hepatic (80%) and pancreatic (80%) iron

overload were significantly higher among patients with cardiac iron overload. Moreover, the rate of hepatic (84%) and cardiac (22%) iron deposition were also increased among patients with pancreatic iron overload. This finding may be useful in the approach to patients with cardiac, and pancreatic iron burden. A very recent multicenter study with more than 1000 thalassemia major patients showed that patients with cardiac fibrosis and cardiac complications had significantly lower pancreas T2* level [37].

Researchers concluded that pancreatic iron overload is an indicator for cardiac iron burden. Cardiac iron overload can be managed through more aggressive treatment such as a combined chelator because chelation therapy acts on hepatic and extrahepatic tissue and extrahepatic organs release iron very slowly out of the body [31, 35], but also deferiprone in monotherapy [36].

The cardiac iron burden was found associated with diabetes in the recent literature [32]. We found consistent with the literature that the cardiac T2* value was negatively correlated with fasting blood glucose. Similarly, patients with diabetes and thalassemia can develop myocardial fibrosis. Therefore, disorders in carbohydrate metabolism should be screened in patients with cardiac iron burden, or cardiac complications should be evaluated in patients with diabetes.

Patients with short stature were found prone to cardiac iron overload. In the literature, we found no exact correlation with short stature, and heart iron burden. Short stature can originate from deficiency of growth hormone, lack of growth factors due to liver dysfunction, degenerated bone metabolism, and disease chronicity [33, 34]. The chronic process of iron overload in hepatic and extrahepatic tissues can affect hormonal regulation, which in turn can cease the increase in height. The limitation of our study is its retrospective design, the restricted number of patients with significantly smaller and younger study cohorts, and lack of a control group.

Conclusion

In the present study, we found that two out of three patients with thalassemia had an endocrine complication. The serum ferritin level of patients should be kept below 840 ng/mL by the administration of appropriate chelation therapy to avoid iron burden in endocrine organs. Patients with cardiac iron burden should be closely followed up in terms of endocrine complications.

Figures

MRI of Organs

MRI values in organs; green zone, yellow zone and red zone respectively:
Heart T2* >20; 10-20; <10 ms; Pancreas R2*<48; 48-150; >150 Hz and Liver T2* >6.7; 1.4-6.7; <1.4 ms

Figure 1

Severity of iron burden of organs in participants
