Abstract

21

22   The Mikawa Bay Region, central Japan, is characterized by many active faults recording

23   Quaternary activities. It is, however, difficult to understand the overall tectonic character of

24   the region due to a thick sedimentary cover. We report the first finding of Neogene basin

25   inversion in southwest Japan by estimating the depth and structure of the basement surface in

26   the Mikawa Bay Region by analyzing gravity data. Our gravity basement map and

27   two-dimensional density-structure model automatically determined using the genetic

28   algorithm revealed a half-graben bounded on the south by the north-dipping Utsumi Fault.

29   The motion of the Utsumi Fault, which inverted from normal faulting during the Miocene to

30   recent reverse faulting, indicated the inversion of the half-graben. The timing of the inversion

31   of the fault motion, i.e., the reverse faulting of the Miocene normal fault, can be compared

32   with an episode of basin inversion observed at the eastern margin of the Japan Sea,

33   northeastern Japan. The Takahama Fault in the southwestern part of the Nishi–Mikawa Plain

34   is considered to have formed as a result of the backthrust of the Utsumi Fault under inversion

35   tectonics. If the Takahama Fault is indeed the backthrust fault of the Utsumi Fault, the root of

36   the Takahama Fault may be deep such that the Takahama Fault is seismogenic and linked to

37   the 1945 Mikawa earthquake.

43

44 **Introduction**

45   The Japan Arc is situated in a zone of plate convergence, where crustal activity such as

46 earthquakes is common (Fig. 1 a). Throughout the Japan Arc, there are many faults that are

47 potentially active in the Quaternary. This article is the case in the Mikawa Bay Region, central

48 Japan, close to the Nagoya area, one of Japan's largest urban areas. The evaluation of fault

49 activity is an important issue in Japan; however, it is difficult to understand the overall

50 tectonic characteristics of these active faults due to thick sediments and sea area in the

51 Mikawa Bay Region. The Nishi–Mikawa Plain, also called the Okazaki Plain, a central part of

52 the Mikawa Bay Region, is filled with thick sedimentary rocks and sediments (~1000 m) from

53 the Miocene to Holocene. Quaternary crustal movements of Chita Peninsula, which is

54 surrounded by the sea (i.e., Chita Bay, Mikawa Bay, and Ise Bay), have been well recorded as

55 the elevation distribution of several marine terraces in the Pleistocene (e.g., Makinouchi

56 1979).

57 In this study, we focus on the geological structure of the Mikawa Bay Region in order to

58 understand local fault dynamics. Several geological and geophysical studies have been

59 previously undertaken for disaster mitigation in this region. Research conducted by the local

60 government has revealed the basement structure beneath the plain and peninsula (Aichi

61 Prefecture, 2002a, 2002b, 2004, 2005). The top of the basement deepens to the west, although

62 basement rocks are exposed in the eastern area of the plain. The deepest part of the basement

63 lies beneath the Chita Peninsula, where its depth is greater than 1,500 m (Aichi Prefecture,

64 2002a). Although active faults in the northwest part of the Nishi–Mikawa Plain and the

65 northern part of the Chita Peninsula have been investigated using seismic reflection surveys to

66 image their structures (Aichi Prefecture, 1996), the active faults in the central part of the

67 Nishi–Mikawa Plain and the south part of Chita Peninsula remain under discussion. One such

68 active fault, the Utsumi Fault, runs along the southwestern coast of the Chita Peninsula.

69 Although the Utsumi Fault is expected to play an important role in the formation of the Chita

70 Peninsula, its subsurface structure is poorly known. Furthermore, a comprehensive

71 understanding of the Takahama Fault, which distributes around a large urban area, has yet to

72 be made clear.

73 In this study, we compiled existing gravity data together with our own gravity measurements

74 in the northern part of the Mikawa Bay Region to image the structure of the basement beneath

75 the Nishi–Mikawa Plain and Chita Peninsula. We revealed the detailed structure including the

76 active faults' orientation using a genetic algorithm (GA) in the central part of the Nishi–

77 Mikawa Plain (i.e., the Takahama Fault) and along the southwestern edge of the Chita

78 Peninsula (i.e., the Utsumi Fault). Then, we discussed the local tectonics with a basin

79 inversion and the conjugate relationship between the Utsumi and Takahama Faults.

80

81 **Study area**

82   The Mikawa Bay Region is located in the southern part of central Japan (Figs. 1 and 2). The

83 Nishi–Mikawa Plain is in the northern Mikawa Bay Region, and the Chita Peninsula is at the

84 west of the Nishi–Mikawa Plain, across Chita Bay. The Nishi–Mikawa Plain is mainly

85 covered with the Pleistocene terraces and alluvial lowland, and its topography is relatively flat

86 (Makimoto et al., 2004). On the other hand, the Chita Peninsula has a relatively high

87 topography. The hills of the Chita Peninsula approximately extend along the N–S trend and

88 primarily consist of the Middle Pleistocene terrace deposits (e.g., the Taketoyo and Noma

89 formations) and Pliocene sedimentary rocks (the Tokai Group), whereas the Miocene

90 sedimentary rocks (the Morozaki Group) are exposed in the southern part of the peninsula

91 (Kondo and Kimura, 1987). The Hazu Mountains and Mikawa Mountains, both of which

4

92   consist of Mesozoic metamorphic rocks and granite, are located to the southeast and northeast

93   of the Nishi–Mikawa Plain, respectively. The Atsumi Peninsula is elongated in an ENE-WSW

94   direction south of the Nishi–Mikawa Plain across Mikawa Bay. Ise Bay lies at the west of the

95   Chita Peninsula. The largest plain close to this region, the Nobi Plain, is situated to the

96   northwest of the Chita Peninsula.

97   Active faults occur in and around the Nishi–Mikawa Plain and throughout the southern part

98   of the Chita Peninsula (Fig. 2). Long-term evaluations along major active faults in Mikawa

99   Bay Region are reported by the Headquarters for Earthquake Research Promotion (2002;

100   2004). The Sanage–Sakaigawa Fault is a NE–SW trending and the Odaka–Obu Fault is a

101   NNW–SSE trending in the northern Nishi–Mikawa Plain. The Ise-wan Fault is along the

102   northeastern edge of the Chita Peninsula. The Kagiya Fault is NNW–SSE trending in the

103   northern the Chita Peninsula. The active faults in the northwest part of the Nishi–Mikawa

104   Plain and the northern part of the Chita Peninsula such as the Ise-wan Fault (Okada et al.

105   2000) as well as the Odaka–Obu and Kagiya faults (Aichi Prefecture, 1996) have been

106   investigated using seismic reflection surveys to image their structures.

107   In this paper, we focused on the three major active faults in central-west part of Mikawa Bay

108   Region whose structures remain under discussion: the Utsumi, Takahama and Kou faults. The

109   Utsumi Fault trends NW–EW along the steep cliffs of the southern edge of the Chita

110   Peninsula (Fig. 2). A closed depression suggesting a tectonic relief is recognized along the

111   base of the steep cliffs in submarine topography (Goto, 2013). Uplifting on the NE side of the

112   Utsumi Fault is recorded in subsurface Quaternary sediments discovered *via* shallow seismic

113   reflection surveys (Chujo and Suda, 1971; 1972). This uplifting is believed to have formed the

114   present topography of the southern Chita Peninsula. Gravity surveys around the southern part

115   of the Chita Peninsula indicate a remarkably low Bouguer anomaly, suggesting thick

116   sedimentary rocks and a deep basement surface (Chujo and Suda, 1972). Deep seismic

117   surveys able to image the shape of basement in this region have not yet been conducted. The

118   Takahama Fault is a NW–SE trending active fault in the central Nishi–Mikawa Plain.

119   Topographic features along the fault are, however, ambiguous in its southeastern part but clear

120   in the northwestern part. The southwest-dipping reverse fault was discovered by seismic

121   surveys conducted in the northwest (Aichi Prefecture, 1996). Nonetheless, geophysical

122   surveys, such as seismic surveys, have not yet been conducted in the southeastern part of the

123   fault, with the exception of several boring surveys (e.g., Abe et al., 2019a; 2019b). The Kou

124   Fault, another active one in the research area, is a N–S trending and east-dipping (45°E)

125   reverse fault (Kondo and Kimura, 1987). Although the Kou Fault is thought to have been

126   active at the southern end of the N–S Kagiya fault zone traversing the Chita Peninsula, its slip

127   rate is unknown (The Headquarters for Earthquake Research Promotion, 2004). Some studies

128   have classified the Kou Fault as estimated active fault which is not directly observed on the

129   ground surface but is inferred from topography (Imaizumi et al., 2018).

130   The Mikawa earthquake (Mw 6.6) occurred in the Mikawa Bay Region on January 13, 1945,

131   causing more than 2,300 causalities (Iida, 1978). Kikuchi et al. (2003) analyzed seismograms

132   of the Mikawa earthquake and revealed that its source was a NW–SE trending reverse fault

133   with a slight left-slip component. The slip distribution mainly consisted of two asperities: one

134   near the hypocenter and the other, with which the heavily damaged area is well correlated,

135   10–15 km to the northwest from the hypocenter (Kikuchi et al., 2003). Yamanaka (2004)

136   reanalyzed the slip distribution in the 1945 earthquake using additional seismograms; this

137   revised result also showed a large slip in the northwest part of the fault model. Several other

138   studies concerning the Mikawa earthquake have noted the predominant role of N-S or E-W

139   trending faults (i.e., the Yokosuka and Fukozu faults) in the southeast part of the Nishi–

140   Mikawa Plain and the eastern part of the Mikawa Bay. Ando (1974) interpreted the ground

141   movements as observed geodetically in terms of a N-S striking fault. Takano and Kimata

142   (2009) reexamined the ground deformation caused by the earthquake through removing

143   interseismic deformation and coseismic deformation resulting from the 1944 Tonankai

144   earthquake (Mw 7.9), which occurred ~150 km southwest off the Mikawa Bay Region. The

145   estimated slips in the 1945 earthquake for the Yokosuka and Fukozu faults are 1.4 m and 2.5

146   m, respectively. Sugito and Okada (2004) compiled geomorphic and geologic features of the

147   surface rupture associated with the earthquake, and suggested that nearly pure thrust faulting

148   along the southern N-S trending section was the predominant mode of surface faulting during

149   the earthquake. The two prevailing models (i.e., the NW–SE trending fault and the N-S

150   trending fault) are not consistent, thus the structure of the source fault of the Mikawa

151   earthquake is still under discussion.

152

153   **Datasets**

154   We used publicly available gravity datasets and an additional dataset that we observed across

155   the southeast part of the Takahama fault in the central Nishi–Mikawa Plain. Most of the

156   Mikawa Bay Region is covered by the publicly available datasets (Yamamoto et al., 2011;

157   Geological Survey of Japan, 2013; Gravity Research Group in Southwest Japan, 2001) that

158   we used for our analysis (Fig. 3a). Furthermore, in order to investigate the detailed structure

159   of the southwest part of the Takahama fault, we conducted additional gravity surveys at 57

160   gravity stations (Supple. Table 1) using a Lacoste and Romberg gravimeter (G-304). The

161   network real-time kinematic techniques with the Virtual Reference Station method using

162   Trimble R10 were applied to determine the location of the gravity stations. Bouguer

163   anomalies were calculated with standard corrections (GSJ Gravity Survey Group, 1989) for

164　free-air, Bouguer, terrain and atmosphere, and normal gravity was removed in accordance

165　with the Geodetic Reference System 1980 (GRS80). Terrain corrections were applied for a

166　range of 60 km using the 30-m gridded terrain data compiled by Murata et al. (2018). This

167　30-m gridded terrain data in the study area mainly comprises 5- and 10-m gridded digital

168　elevation map generated by the Geospatial Information Authority of Japan (GSI) and M7000

169　series digital bathymetry data provided by the Marine Information Research Center. The

170　reduction density of 2.3 g/cm^3 was used to obtain the Bouguer anomaly. This reduction

171　density was visually selected using the Nettleton method (Nettleton, 1939) and allows the

172　removal of topographic effects arising from sedimentary rocks exposed in the Chita Peninsula

173　and Nishi–Mikawa Plain (Fig. 3b).

174　　We used available elevation data of the basement surface to constrain the basement

175　structure. We collected the elevation data from publicly available sources (Aichi Prefecture

176　2000; 2004; Kuwahara, 1982; Ministry of Land, Infrastructure, Transport and Tourism, 2008;

177　National Research Institute for Earth Science and Disaster Resilience 2019 and Yamada et al.

178　1984) and originally compiled in this study from boring data provide by Aichi Prefecture,

179　Nishio City (Supple. Table 2). We also used geological maps to obtain some locations where

180　the basement exposed to the ground surface (National Institute of Advanced Industrial

181　Science and Technology, 2020b) (Supple. Table 2).

182

Methods

184   We estimated the structure of the basement surface (i.e., the thickness of the overlying

185 sediments) in the Mikawa Bay Region by analyzing gravity anomaly data.

Gravity basement analysis

187   To investigate the structure of the basement surface in the study area, we first estimated the

188 regional trend of the Bouguer anomaly and obtained the optimal density contrast between the

189 sediment/sedimentary rock and the basement rocks. Observed Bouguer anomaly contains

190 mainly two components: regional trend originated by deep/large structure and local effects of

191 the shallow geology. The regional trend of the Bouguer anomaly is caused by the deep/large

192 structure such as subducting slab beneath Japan and/or the Moho structure of the region, and

193 therefore the regional trend is usually observed as long-wavelength components. On the other

194 hand, shallow geological structure such as the distribution of different rock types or sediment

195 thickness, which forms the focus of this study, produces short wavelength Bouguer anomalies.

196 In the study region, rocks can be divided into two types based on density: lower-density

197 sediments/sedimentary rocks, and higher-density basement rocks (i.e., granite and

198 metamorphic rocks). The representative densities of these rock types exposed in this region

199 are ~1.4–2.3 g/cm^3 for sediments/sedimentary rocks and ~2.5–2.9 g/cm^3 for granite and

200   metamorphic rocks, respectively (Schön 2004). Knowing the density contrast between these

201   two types of rocks allows us to estimate the thickness of the sediments/sedimentary rock

202   covering the basement rocks from the residual Bouguer anomaly after the removal of the

203   regional trend.

204   The regional trend of the Bouguer anomaly (long-wavelength components) and its optimal

205   density contrasts are estimated based on the elevation of the basement observed in the

206   borehole or outcrop. The observed Bouguer anomaly (g_{BA}) with suitable terrain correction can

207   be explained as the summation of the regional trend ($g_{regional}$) and local effects

208   (short-wavelength component) ($g_{sediments}$).

209    $$g_{BA} = g_{sediments} + g_{regional}$$

210   The regional trend is assumed to be expressed by the polynomial curved surface as follows:

211    $$g_{regional} = f(x, y|s),$$

212   where x and y are coordinates in the rectangular coordinate system and s is the coefficient of

213   the polynomial curved surface (f). The local effect is assumed to be derived from the density

214   contrast between sediments/sedimentary rocks and basement rocks and the thickness of the

215   sediments/sedimentary rocks. We modeled the effect of the sediments/sedimentary rock cover

216   below sea level using an infinite horizontal plate:

217    $$g_{sediments} = -2\pi G \Delta \rho H,$$

11

218   where G is the gravitational constant (6.674×10^{-11} m³/kg·s²), $\Delta\rho$ is the density contrast

219   between the sediments/sedimentary rocks and the basement rocks, and H is the thickness of

220   the sediments/sedimentary rocks below sea level (i.e., elevation of the basement surface).

221   Here, the equation required to express the observed Bouguer anomaly can be written as

222   follows:

223 $$g_{BA} = -2\pi G\Delta\rho H + f(x, y|s).$$

224   We obtained the regional component of the polynomial curved surface together with the

225   optimal density contrast by solving the least squares problem for the basement surface

226   elevation below sea level (H_i) at the boring site (x_i, y_i), and then the observed Bouguer

227   anomaly at the site (g_{BAi}):

228 $$\sum_{i=1}^{N} [g_{BA\,i} + 2\pi G\Delta\rho H_i - f(x_i, y_i|s)] \rightarrow min,$$

229   where N is the number of the sites at which the depth of the basement and the Bouguer

230   anomaly is known. Minimizing the least square problem is achieved by finding the least

231   square solution to the following simultaneous equations:

232 $$\begin{bmatrix} F_1 \\ F_2 \\ \vdots \\ F_N \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1M} & H_1 \\ A_{12} & A_{22} & \cdots & A_{2M} & H_2 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ A_{N1} & A_{N2} & \cdots & A_{NM} & H_N \end{bmatrix} \begin{bmatrix} s_1 \\ s_2 \\ \vdots \\ s_M \\ 2\pi G\Delta\rho \end{bmatrix},$$

233   where $\mathbf{A}$ is the function of the coordinate (x, y). This formula can be written in $\mathbf{F} = \mathbf{As}$. Then,

234   the solution can be found by $\left(\mathbf{A}^{\mathrm{T}}\mathbf{A}\right)\mathbf{s} = \mathbf{A}^{\mathrm{T}}\mathbf{F}$.

235   We used 85 control points for the known elevation of the basement surface. The elevation

236   of the basement at some control points is higher than sea level. For these points, the effect of

237   basement topography above sea level on the Bouguer anomaly should be eliminated by

238   applying appropriate corrections (free-air, Bouguer, and terrain) to the typical density of

239   basement rock (Fig. 4). Hence, we calculated the gravitational corrections for each point at

240   which the basement surface is above sea level, using a widely accepted reduction density of

241   2.67 g/cm^3 for granitic rocks. We calculated the corrections for the remainder of the points

242   using a reduction density of 2.3 g/cm^3 according to the Nettleton method outlined above.

243   We solved the least square problem by using the 85 control points and setting a 2nd order

244   polynomial curved function for the regional trend of the Bouguer anomaly. We employed the

245   polynomial curved function for the regional trend following that of Makino and Endo (1999)

246   (i.e., $f\left(x, y \mid s\right) = s_1 x^2 y^2 + s_2 x^2 y + s_3 x^2 + s_4 xy^2 + s_5 xy + s_6 x + s_7 y^2 + s_8 y + s_9$),   although it is

247   different from the general 2nd order polynomial function. Thereafter, we obtained the optimal

248   density contrast as -0.376 g/cm^3 (i.e., a sediment density of 2.294 g/cm^3) (Fig. 5) with the

249   coefficients of the 2nd order polynomial curved function (Table 1). The obtained optimal

250   density is almost the same as the value set for the sediments/sedimentary rock justified by

251   using the Nettleton method (2.3 g/cm^3). The regional trend of the Bouguer anomaly along the

13

252   2nd order polynomial curved surface is highest in the southeast region and gradually decreases

253   toward the northwest (Fig. 3c). This regional trend is consistent with results reported in the

254   Aichi Prefecture (2002a). The estimation error at the control points is approximately ± 200 m

255   according to the difference between the observed elevation and the calculated elevation of the

256   basement surface (Fig. 6).

257   Finally, we obtained a map of the basement surface by extracting the regional trend from the

258   observed Bouguer anomaly (Fig. 3d) and multiplying the constants of the infinite horizontal

259   plate $(0.0158 = -2\pi G(-0.376)$ mgal/m) (Fig. 7).

260

261   **Detailed modeling of the basement profile**

262   The estimation of the elevation of the basement surface assumes that the infinite horizontal

263   plate is effective for determining the overall structure but unsuitable for the imaging non-flat

264   structures (e.g., faults and slops). Hence, we conducted additional two-dimensional analysis to

265   model the non-flat structures and to illuminate the detailed structure of the region, including

266   the Utsumi and Takahama faults. We set a SW-NE trending survey line from the southwest of

267   the Chita Peninsula to the central part of the Nishi–Mikawa Plain (Fig. 2b). The initial model

268   was set as the profile of the gravity basement model estimated in the previous step. We then

269   modified the initial model by adding the Utsumi and Takahama faults. Although we also

270   attempted to model the Kou Fault crossing the survey line, we were unable to constrain the

271   optimal solution because the gravity data lacked sufficient sensitivity on deep and minor

272   structures related to this fault (see details in the Results section). The validity of the model

273   was evaluated by fitting the observed Bouguer anomaly, which is detrended from the regional

274   trend. Gravity stations within 0.5 km onshore and 1.0 km offshore relative to the survey line

275   were used. To select the best fit parameters, we employed the genetic algorithm (GA), a

276   method for solving optimization problems based on a natural selection process that mimics

277   biological evolution (e.g., Goldberg 1989). The method starts from an initial random

278   population, comprising a number of individuals, which are vectors of model parameters, and

279   iteratively improves the estimated solution. At each iteration, fitness to the objective solution

280   is evaluated for each individual gives. The elites, which are fittest individuals, are selected for

281   cross-over to produce offspring that replace the least fit individuals of the current iteration. A

282   small percentage of this new population is arbitrarily mutated, depending on a given mutation

283   rate, so different areas of the search space can be explored. This mutation helps avoid local

284   minima in the optimization process. The new population is also evaluated, allowing only the

285   fittest individuals to survive, and the process is repeated. Therefore, the GA which is able to

286   solve nonlinear global optimization problems is suitable to find the best parameter set in our

287   model.

288   We obtained the optimal basement model as follows. The synthetic Bouguer anomaly was

289   calculated from the initial model with estimated density contrast (-0.376 g/cm^3) *via* the

290   two-dimensional Talwani's method (Talwani, 1973). Although the overall calculated Bouguer

291   anomaly based on the initial model is consistent with the observed Bouguer anomaly, some

292   discrepancy is observed, especially around the faulted areas (green line in Fig. 8). To reduce

293   these discrepancies, we set parameters to modify the basement structure: the dip of the Utsumi

294   Fault, the dip of the Takahama Fault, the depth shift in the southwest part of the region, the

295   depth shift in the northeast part of the region, the tilt correction of the basement between the

296   Chita Peninsula and Nishi–Mikawa Plain, and the position of the center of tilt correction (see

297   Supple. Figure 1). The dip of the Utsumi Fault in the deep basement is unknown because the

298   depth of the seismic image across the Utsumi Fault is too shallow (~100 m in depth) to

299   capture the shape of the basement (Chujo and Suda, 1971; 1972). Hence, we set the dip of the

300   Utsumi Fault to range from 30°E to 30°W (i.e., 30° to 150° from the east). The dip of the

301   southeast part of the Takahama Fault, through which the survey line passes, is also unknown,

302   although the dip of the northwest part of the fault was estimated to be 70° to 80°W by seismic

303   surveys (Aichi Prefecture, 1996). Hence, we set the dip of the Takahama Fault to range from

304   30°E to 30°W (i.e., 30° to 150° from the east). The tip (surface position) of the Utsumi and

305   Takahama faults were fixed according to previous studies (Imaizumi et al., 2018; Abe et al.,

306 2019a; 2019b); the tip of the Utsumi Fault was set at 0 km (i.e., with its origin in the

307 horizontal direction), while the tip of the Takahama Fault was set at 22.98 km. Even in the flat

308 basement, the synthetic Bouguer anomaly calculated from the initial model is systematically

309 lower than the observed Bouguer anomaly. Therefore, we set the depth shift in the southwest

310 part (−10–0 km in the horizontal direction) and the northeast part (22.98–30 km in the

311 horizontal direction) to range from −0.2 to 0.2 km and −0.1 to 0.1 km in the vertical direction,

312 respectively. A tilt correction for the basement between the Chita Peninsula and the Nishi–

313 Mikawa Plain ranges from −2° to 2°. The center of the tilt correction ranging from 15 to 18

314 km was also set to provide parameters that fit the lowest Bouguer anomaly observed in the

315 Chita Peninsula.

316 The synthetic Bouguer anomaly at each observation point was calculated by the

317 two-dimensional Talwani's method using a density-structure model with the parameters

318 outlined above. The parameter set which produces the best fit model was searched using the

319 GA (Table 2; Fig. 8 & 9). We set that the elite count and the cross-over fraction were set to

320 5% of the population size and 0.8, respectively. The optimization was terminated when the

321 average change in the fitness value is small enough ($1.0e^{-6}$). To validate the robustness of the

322 GA analysis, we ran the GA 10 times and obtained almost the same results every time, within

323 the range of a few degrees or meters, which is considered sufficient accuracy for the

17

324   following discussion (Suppl. Table 3 and Suppl. Fig. 2). We selected the parameter set

325   showing the lowest error from the 10 sets as the optimal parameter set (Table 2).

326

327   **Results**

328   **Basement surface structure around the Nishi–Mikawa Plain**

329   The structure of the basement surface around Mikawa Bay Region is depicted from the

330   Bouguer anomaly (Fig. 7). The basement surface is shallow at the east side of the Nishi–

331   Mikawa Plain, consistent with the exposure of basement rocks in the Mikawa Mountains and

332   Hazu Mountains east of the Nishi–Mikawa Plain. The basement surface deepens from the

333   Nishi–Mikawa Plain to the Chita Peninsula, where its depth is greater than 1,500 m. This

334   trend is consistent with the results of the seismic survey conducted by Aichi Prefecture (2004).

335   The depression of the basement beneath the Chita Peninsula continues to the north of the

336   Nishi–Mikawa Plain.

337   A NNW–SSE elongated basement high exists in Ise Bay to the west of the northern Chita

338   Peninsula (Fig. 7); we interpret it to be caused by reverse faulting on the Ise-wan Fault that

339   was mapped by Okada et al. (2000). The basement surface becomes considerably shallow

340   toward the west across the Utsumi Fault. Its depth in Ise Bay, far west of Chita Peninsula is,

341   however, inconsistent with results obtained by the seismic reflection survey (Iwabuchi et al.,

342   2000). This area, the Ise Bay far west of Chita Peninsula, is the west edge of our study field,

343   where no boring sites were obtained to control basement surface, thus the regional trend of the

344   estimated Bouguer anomaly might be inappropriate in this region.

345

346   **Fault-related basement surface structure in the Mikawa Bay Region**

347   The depth of the basement surface drastically changes across the Utsumi Fault (Fig. 8). The

348   orientation of the Utsumi Fault indicates a structure like a normal fault that is high dip angle

349   (~70°E) and that the vertical offset of the top-basement horizon is ~2000 m (Fig. 8). The

350   Takahama Fault is a reverse fault with a dip angle of ~60°E (Fig. 8). This dip is consistent

351   with the fault dip observed by seismic-reflection profiling across the northwestern part of the

352   Takahama Fault (Aichi Prefecture, 1996). The gap between the hanging wall is ~200 m,

353   which is relatively smaller than that of the Utsumi Fault. The basement surface tilts and

354   deepens from the Takahama Fault to the Utsumi Fault.

355   We attempted to incorporate the basement surface structure of the Kou Fault by including

356   the Kou Fault with a 45°E dip. It is, however, difficult to constrain the structure arising from

357   the Kou Fault. Even when setting the opposite geometry to that of the basement (i.e., reverse

358   fault and normal fault), both synthetic Bouguer anomalies calculated from the conflicting

359   models are within the range of the observed Bouguer anomaly (Fig. 10). The gravitational

360   signal from the resulting small, deep structure is dull, such that the signal of the basement

361   surface topography related to the Kou Fault cannot be constrained in our analysis.

362

363   **Discussion**

364   **Inversion tectonics in the Mikawa Bay Region**

365   The topographic features of the basement surface depict a half-graben structure beneath the

366   Chita Peninsula. Depression of the basement surface beneath the Chita Peninsula has been

367   noted in previous studies (Aichi Prefecture, 2002a; 2004; Chujo and Suda, 1972). We found

368   that the Utsumi Fault indicates a normal fault structure with a large gap, and the tilted

369   basement surface forms the hanging wall of the Utsumi Fault (Fig. 8). These structural

370   features correspond to a large half-graben structure in the Mikawa Bay Region, where the

371   Utsumi Fault is the edge fault of the half-graben.

372   The geometry of the basement surface and uplift forming the Chita Peninsula suggest the

373   inversion tectonics of the half-graben in the Mikawa Bay Region. A discrepancy between the

374   recent reverse faulting and the depressed basement beneath the Chita Peninsula was identified

375   in a previous study (Chujo and Suda, 1972). The recent NE side up reverse faulting (i.e., uplift

376   of the Chita Peninsula side) is recorded in the Quaternary sediments. On the other hand,

377   Miocene normal faulting of the Utsumi Fault is suggested from the thick Miocene sediments

378   on the hanging wall (Aichi Prefecture, 2005). Therefore, the motion of the Utsumi Fault is

379   shown to have changed from normal faulting in the Miocene to recent reverse faulting (Aichi

380   Prefecture, 2005). This change of motion is interpreted as inversion tectonics related to the

381   half-graben structure discovered herein (Fig. 11).

382   The lack of knowledge of the geometry of the basement surface by Kou Fault makes it

383   difficult to clarify the role of Kou Fault in the inversion. As shown above, the gravity anomaly

384   could not constrain the structure arising from the Kou Fault. This fact suggests that a

385   displacement of the Kou Fault is less than that of the Utsumi Fault during the inversion

386   process. Therefore, the Kou Fault may be a minor branch fault of the Utsumi Fault, which is

387   the master fault of the inversion. In contrast, the N–S trending Kou Fault is oblique to the

388   NW–SE trending Utsumi Fault. This geometrical discrepancy suggests an irrelevance between

389   the Kou Fault and the Utsumi Fault, and the Kou Fault may have different history to the

390   Utsumi Fault. To conclude the abovementioned issues, more detailed structural exploration is

391   required.

392   The tectonic history of the Chita Peninsula has been reconstructed using the

393   sediments/sedimentary rocks observed in the region. The thick Miocene sedimentary rocks

394   (Morozaki Group) filled the hanging wall of the Utsumi Fault; hence the motion of the

395   Utsumi Fault was normal in the Miocene (Aichi Prefecture, 2005). The half-graben structure

396 was formed during this extensional stage. Subsequently, Pliocene sedimentary rocks (Tokai

397 Group) were folded with the axis of WNW-ESE before the Middle Pleistocene (Makinouchi,

398 2019). This may suggest that the region was under moderate NNE-SSW compressional stress

399 at this time, which also accounts for the fact that the Utsumi Fault which trends NW–SE was

400 hardly reactivated during this stage. The Utsumi Fault reactivated as a reverse fault around 0.5

401 Ma (following the depositional age of the Middle Pleistocene Taketoyo Formation)

402 (Makinouchi, 2019). The displacement of the reverse faulting was, however, insufficient to

403 recover the gap formed during normal faulting in the Miocene.

404   The tectonic history of the inversion structure in the Chita Peninsula is comparable to

405 inversion tectonics at the eastern margin of the Japan Sea in northeast Japan. The inversion

406 structures in the eastern margin of the Japan Sea are the most completely described inversion

407 structures in Japan (e.g., Okamura et al., 1995; Morijiri, 1996). Normal faults were formed

408 during the Early to Middle Miocene, and were reactivated in the Pliocene to Quaternary

409 (Okamura et al., 1995). Periods of normal fault formation and reactivation in the eastern

410 margin of Japan Sea in northeast Japan coincide with those in the Chita Peninsula. This

411 episode of Miocene normal faulting is believed to be related to the opening of the Japan Sea,

412 whereas the reactivation of reverse faulting motion is considered to be due to E-W

413 compression resulting from the present tectonic setting. Although the tectonic history between

414   central and northeast Japan differs after the opening of the Japan Sea (e.g., Hayashida et al.,

415   1991; Jolivet et al., 1995; Lallemand and Jolivet, 1986; Otofuji et al., 1985), the deduced

416   agreement in the period of the inversion tectonics can be considered a clue to understanding

417   the tectonic dynamics of the Japan Arc.

418   In particular, the onset of positive tectonic inversion in Chita (~0.5 Ma) is significantly

419   younger than that in NE Japan (3–5 Ma). However, the period of normal faulting is the same

420   between both the regions. Previous active fault studies also suggest that the onset of the

421   present tectonic settings and the onset of present active faulting are early in NE Japan and late

422   in SW Japan (e.g., Doke et al. 2012; Miyakawa and Otsubo 2017). This difference in the onset

423   of the positive tectonic inversion and the active faulting could yield a new finding.

424

425   **The Takahama Fault under inversion tectonics**

426   Our results also enable us to discuss the role of the Takahama Fault in the inversion tectonic

427   system in the Mikawa Bay Region. The Takahama Fault constitutes the NE edge of the

428   half-graben (Figs. 8 and 9). Its basement surface is tilted from the Takahama Fault to the

429   Utsumi Fault, although the basement surface is almost flat northeast of the Takahama Fault.

430   Concurrently, the dip orientation of the Takahama Fault is west dipping. Consequently, the

431   Takahama Fault is a "backthrust" of the Utsumi Fault (east dipping). The backthrusts are well

432   observed in analog inversion tectonics experiments (McClay and Buchanan, 1992) (Fig. 11a).

433   Furthermore, fault traces of both the Takahama and Utsumi Fault observed on the ground

434   surface are NW–SE trending, and both traces are parallel. Such parallel master normal fault

435   and backthrust relationships are observed in three-dimensional analog models reconstructing

436   inversion tectonics (Yamada and McClay, 2004). These geometrical features suggest that the

437   Takahama Fault is a backthrust of the Utsumi Fault, which is the master normal fault of the

438   inversion structure.

439   The initiation of the reverse faulting period of the Takahama Fault also suggests a conjugate

440   relationship with the reverse faulting of the Utsumi Fault. The initiation/acceleration period of

441   the reverse faulting of the Takahama Fault is estimated to be late Middle Pleistocene base on

442   the analysis of boring cores around the southeastern part of the fault (Abe et al. 2019a; 2019b).

443   This period is a similar one as that of the initiation of reverse faulting of the Utsumi Fault

444   implied from the formation of the Chita Peninsula in late Middle Pleistocene (Makinouchi,

445   2019). The simultaneity of the initiation of reverse faulting suggests that the Takahama and

446   Utsumi faults are parts of the same inversion tectonic system.

447   The deep extent of the Takahama Fault within the basement rock cannot be detected by the

448   present gravity survey. However, if the Takahama Fault is the backthrust of the Utsumi Fault,

449   it should reach seismogenic depths. The slip distribution of the 1945 Mikawa earthquake

450   estimated by waveform inversions shows a large slip asperity on the NW–SE trending reverse

451   fault (Kikuchi et al., 2003; Yamanaka, 2004). The location of the northwestern asperity is

452   notably correlated with the heavily damaged area, consistent with the deeper extension of the

453   Takahama Fault (~10 km depth). The strike of the Takahama Fault (N45°W) is parallel to the

454   fault model of the 1945 Mikawa earthquake described by Kikuchi et al. (2003); moreover, the

455   tips of the fault traces are significantly correlated (see, Fig. 2). This agreement suggest that

456   the deep extension of the Takahama Fault can explain the fault model of the northwestern

457   asperity described in Kikuchi et al. (2003) and Yamanaka (2004). The dip of the fault model

458   (30°W) in these studies is, however, lower than the dip estimated in this study (~60°W). This

459   discrepancy may be solved by assuming listric fault geometry in the deeper portion of the

460   Takahama Fault. Based on the leveling data collected by the local government, the 40-cm

461   subsidence of the footwall side (NE side) relative to the hanging wall side along the

462   Takahama Fault in the 1945 Mikawa earthquake (Iida and Sakabe, 1972) supports evidence

463   for reverse faulting of the Takahama Fault during the earthquake. On the other hand, several

464   studies suggest that the N-S trending reverse faults in the southwestward of the Nishi–

465   Mikawa Plain (i.e., the Yokosuka and Fukouzu Faults) were predominant factors in surface

466   faulting during the earthquake (e.g., Ando 1974, Sugito and Okada, 2004; Takano and Kimata,

467   2009). Although remarkable fractures appear on the ground surface along the Yokosuka and

468 Fukouzu faults where the basement rock is shallow or exposed, the thick and soft Quaternary

469 sediment and Miocene to Pliocene sedimentary rocks covering the Takahama Fault (Aichi

470 Pref 2002a, 2002b, 2004, 2005) may reduce the ground deformation along the Takahama

471 Fault. Therefore, the deep extension of the Takahama Fault, the back thrust of the Utsumi

472 Fault, may be one possible source fault for the 1945 Mikawa earthquake, but this remains

473 difficult to conclude unambiguously.

474

475

476

477 **Conclusions**

478 We analyzed gravity data to describe the basement surface structure in the Mikawa Bay

479 Region. The gravity basement map showed the deepening of the basement surface from the

480 Nishi–Mikawa Plain to the Chita Peninsula. Two-dimensional modeling constrained the

481 orientation of the Utsumi and Takahama faults, although the basement surface structure

482 related to the Kou Fault is so minor that the gravity data cannot constrain it. The basement

483 surface structure from the Nishi–Mikawa Plain to the Chita Peninsula revealed a half-graben

484 structure defined by the Utsumi Fault. The inverse motion of the Utsumi Fault, which

485 underwent normal faulting during the Miocene and recent reverse faulting, is interpreted in

486   terms of the inversion tectonics of the half-graben. These inversion tectonics, reflecting the

487   reverse faulting of the Miocene normal fault, are comparable to the basin inversion observed

488   at the eastern margin of the Japan Sea in northeastern Japan. The Takahama Fault in the

489   southwestern part of the Nishi–Mikawa Plain is considered to have formed during the

490   backthrust of the Utsumi Fault under inversion tectonics. If the Takahama Fault is indeed the

491   backthrust fault of the Utsumi Fault, the root of the Takahama Fault may be so deep as to

492   reach the seismogenic zone, suggesting that the Takahama Fault may be the source fault of the

493   1945 Mikawa earthquake.

Figure legends

752 Figure 1. Map showing the tectonic setting of the Japanese islands (a) and the geology of the

753 study area (b) (National Institute of Advanced Industrial Science and Technology 2020b). (a)

754 Thick black lines represent plate boundaries and black arrows represent relative plate motions

755 (after Wei and Seno, 1998). The blue rectangle represents the study area and the green shaded

756   area is the eastern margin of the Japan Sea (see main text for discussion).

757

758   Figure 2. Topography and active faults in the Mikawa Bay Region. Red lines represent the

759   traces of active faults in Figure 1(b) (National Institute of Advanced Industrial Science and

760   Technology, 2020a). The blue line indicates the profile line shown in Figures 8, 9, and 10.

761   The topography is illustrated using the 30 m gridded terrain data compiled by Murata et al.

762   (2018). The top-right panel represents the slip distribution model of the 1945 Mikawa

763   Earthquake (modified after Kikuchi et al., 2003). The increment of contour lines is 0.5 m and

764   the star indicates the epicenter of the 1945 Mikawa Earthquake.

765

766   Figure 3. Bouguer anomaly of the study area. (a) Red dots indicate the location of gravity

767   stations used for this analysis. (b) Bouguer anomaly calculated with a reduced density of 2.3

768   g/cm^3. (c) Regional trend of the Bouguer anomaly. Black dots and crosses represent the

769   boring locations and basement exposing locations, respectively. (d) Residual Bouguer

770   anomaly obtained by deducting the regional trend (c) from the original Bouguer anomaly (b).

771   The topography (a) is illustrated by using the 30 m gridded terrain data compiled by Murata et

772   al. (2018).

773

774   Figure 4. Schematic diagrams showing the calculation of residual Bouguer anomalies at the

775   boring sites and basement exposure points. (a) Definition of the elevation of points (h) and

776   the density of the basement (ρ_b) and one unit of sediments/sedimentary rocks (ρ_s). The

777   elevation of the buried basement surface is represented by H. (b) Gravitational corrections

778   (Δg) (Bouguer, free-air and terrain correction) are calculated using the density of the rock

779   exposed at the observation points. g_n is normal gravity in accordance with the Geodetic

780   Reference System 1980 (GRS80). The corrected Bouguer anomaly (g_{BA}) represents the

781   Bouguer anomaly considered. (c) The residual Bouguer anomaly (g') is obtained by

782   removing the regional trend from the Bouguer anomaly (g_{BA}). The residual Bouguer

783   anomaly must consist of the gravity anomaly from the thickness of the

784   sediments/sedimentary rocks (i.e., the elevation of the basement surface).

785

786 Figure 5. Relationship between the elevation of the basement and the residual Bouguer

787 anomaly at the boring site or basement exposure (Fig. 4). The red line represents the

788 relationship between the elevation of the basement and the residual Bouguer anomaly by

789 using the least square method.

790

791 Figure 6. Difference between the observed elevation of the basement surface and the

792   calculated elevation of the basement surface (see Fig. 5).

793

794   Figure 7. Gravity basement map obtained using the relationship between the depth of the

795   basement and the residual Bouguer anomaly (Fig. 5) based on the the residual Bouguer

796   anomaly map (Fig. 3d).

797

798   Figure 8. Profiles of the Bouguer anomaly (a) and the topography of the basement surface (b).

799   (a) The observed and interpolated residual Bouguer anomalies are represented by the open

800   circles and cyan line, respectively. The interpolated residual Bouguer anomalies come from

801   that of the Fig. 3 (d). The green line and red line represent the calculated Bouguer anomaly

802   from the initial model (green in b) and the optimum model (red in b) using the 2D Talwani's

803   method. (b) The green line represents the initial model extracted from the gravity basement

804   model (Fig. 5) along the survey line. The red line represents the optimum basement model

805   obtained by selecting the best parameters (see Table 2). The black line represents the elevation

806   of the ground surface. The origin of the x-axis is set as the tip of the Utsumi Fault in both a

807   and b.

808

809   Figure 9. Close-up views of the profiles of the Bouguer anomaly (a) and the topography of the

44

810   basement surface (b) around the Takahama Fault. The tip of the Takahama Fault is located at

811   22.98 km. (a) The observed and interpolated residual Bouguer anomalies are represented by

812   open circles and the cyan line, respectively. The interpolated residual Bouguer anomalies

813   come from that of the Fig. 3 (d). The green line and red line represent the calculated Bouguer

814   anomaly from the initial model (green in b) and the optimum model (red in b) using the 2D

815   Talwani's method. (b) The green line represents the initial model extracted from the gravity

816   basement model (Fig. 5) along the survey line. The red line represents the optimum basement

817   model obtained by selecting the best parameters (Table 2). The black line represents the

818   elevation of the ground surface. The origin of the x-axis is set at the tip of the Utsumi Fault in

819   both a and b.

820

821   Figure 10. Profiles of the Bouguer anomaly and the topography of the basement surface with

822   600 m of displacement along the Kou Fault at 2.26 km with a dip of 45°E. (a) Reverse fault

823   structure of the Kou Fault using the optimal basement model. (b) Normal fault structure of the

824   Kou Fault using the optimal basement model. Lines and circles are same as shown in Figure 8.

825   The origin of the x-axis is set at the tip of the Utsumi Fault in both a and b.

826

827   Figure 11. (a) Conceptual models for thrust faults developed by the dip-slip inversion of a

828   normal fault system (modified after McClay and Buchanan, 1992). The white arrow

829   represents normal faulting during the extensional stage. Black arrows indicate reverse faulting

830   during the compressional stage following the extensional stage. (b) Conceptual models for the

831   fault system across the Chita Peninsula and the Nishi–Mikawa Plain (not to scale). The white

832   arrow represents the normal faulting in the extensional stage in Miocene. Black arrows

833   indicate reverse faulting during the compressional stage following extensional stage in the

834   Pliocene to Quaternary.

835

836

837

838

839   Table 1. Coefficient of the polynomial function representing the regional trend of the Bouguer

840   anomaly.

Table 1. Coefficient of the polynomial function represents the regional trend of Bouguer anomaly								
s_1	s_2	s_3	s_4	s_5	s_6	s_7	s_8	s_9
0.00007	0.00149	-0.02301	-0.00089	0.00083	1.34760	-0.01037	-0.88458	13.61115

The s_i is the coefficient of the following function.

$$f(x, y \mid s) = s_1 x^2 y^2 + s_2 x^2 y + s_3 x^2 + s_4 xy^2 + s_5 xy + s_6 x + s_7 y^2 + s_8 y + s_9$$

841   , wher x and y is local cartesian coordinates (km) from coorindates of an origin 137 °E, 35 °N.

842

843   Table 2. Optimum parameters for the 2D basement model.

Table 2. Optimum parameters for the 2D basement model						
Dip of Utsumi Fault (° E)	Dip of Takahama Fault (° W)	Depth Shift of the basement southweset from the Utsumi Fault (km)	Depth Shift of the basement northeast from the Takahama Fault (km)	Rotation of the basement between the Utsumi and Takahama faults (deg to anticlock wise)	Rotation center of between the Utsumi and Takahama faults (km)	Mean absolute error (mgal)

Legend

No:	Station Number
Year, Month, Day and Time: Obsarevation year month day and time in JST (UTC+9)	
Latitude:	Latitude (e.g. 242259.9753 means 24 degrees 22 minutes 59.9753 seconds North)
Longitude:	Longitude (e.g. 1241000.4210 means 124 degrees 10 minutes 00.4210 seconds East)
H:	Observation Point Height (m)
Gobs:	Observed gravity value (mGal)
Gnorm:	Normal gravity value (mGal)
FAC:	Free-air correction value (mGal)
BGC:	Bouguer correction value (mGal / 1.0 g/cm^3)
TI:	Terrain correction value (mGal / 1.0 g/cm^3)
Tw:	Sea water correction value (mGal / 1.0 g/cm^3)
BGA:	Bouguer anomaly (assumed density: 2.30 g/cm^3)

Bouguer Anomaly value can be calculated as

$$BGA = Gobs - Gnorm + FAC + (BGC + TI) \times \rho + Tw \times \rho_w$$

where ρ and ρ_w are the assumed densities of surficial rocks and sea water, respectively.

Supplementary Table 2. Elevation of the basement surface compiled in this study.

Additional Table 2. Elevation of basement top newly compiled in this study

Figures
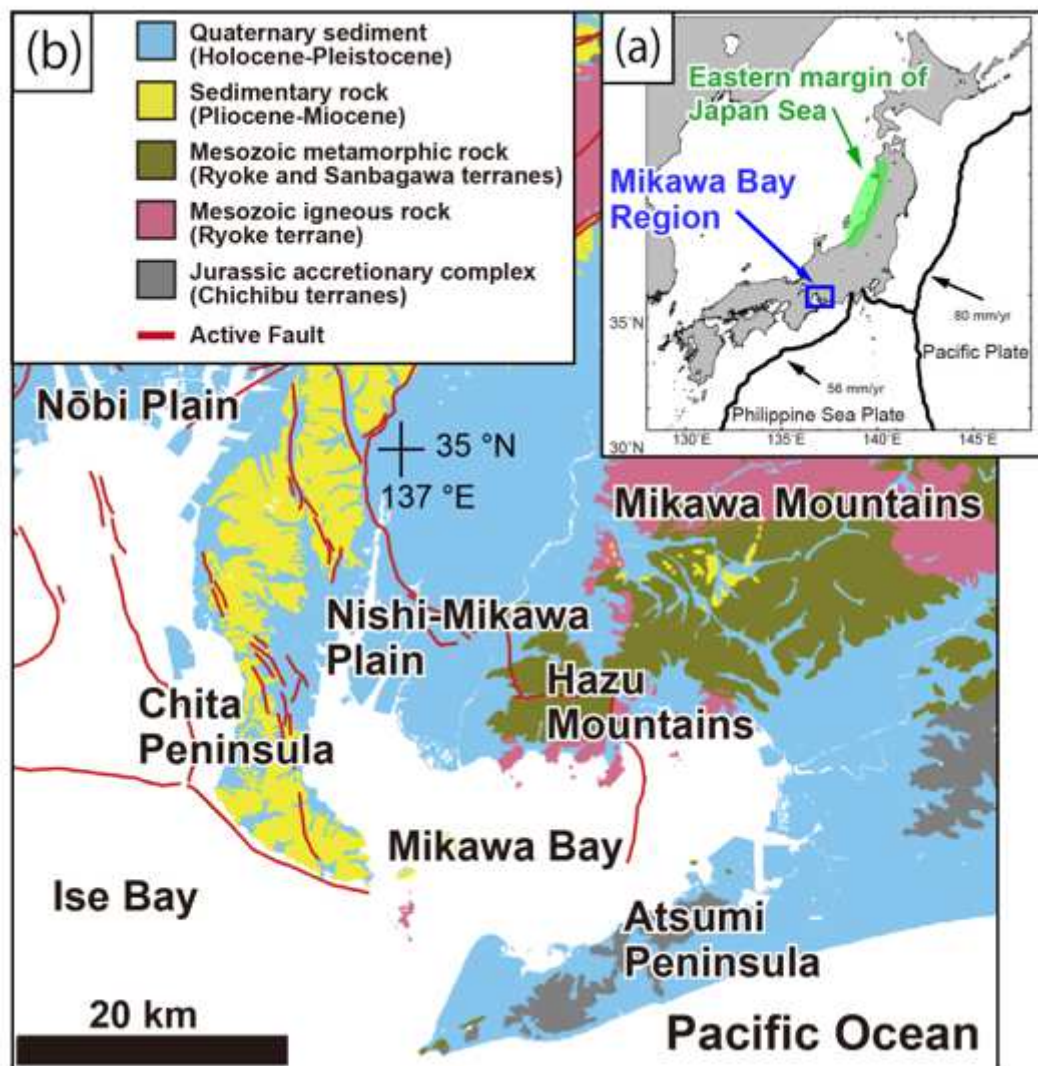

Figure 1

Map showing the tectonic setting of the Japanese islands (a) and the geology of the study area (b) (National Institute of Advanced Industrial Science and Technology 2020b). (a) Thick black lines represent plate boundaries and black arrows represent relative plate motions (after Wei and Seno, 1998). The blue rectangle represents the study area and the green shaded area is the eastern margin of the Japan Sea (see main text for discussion).
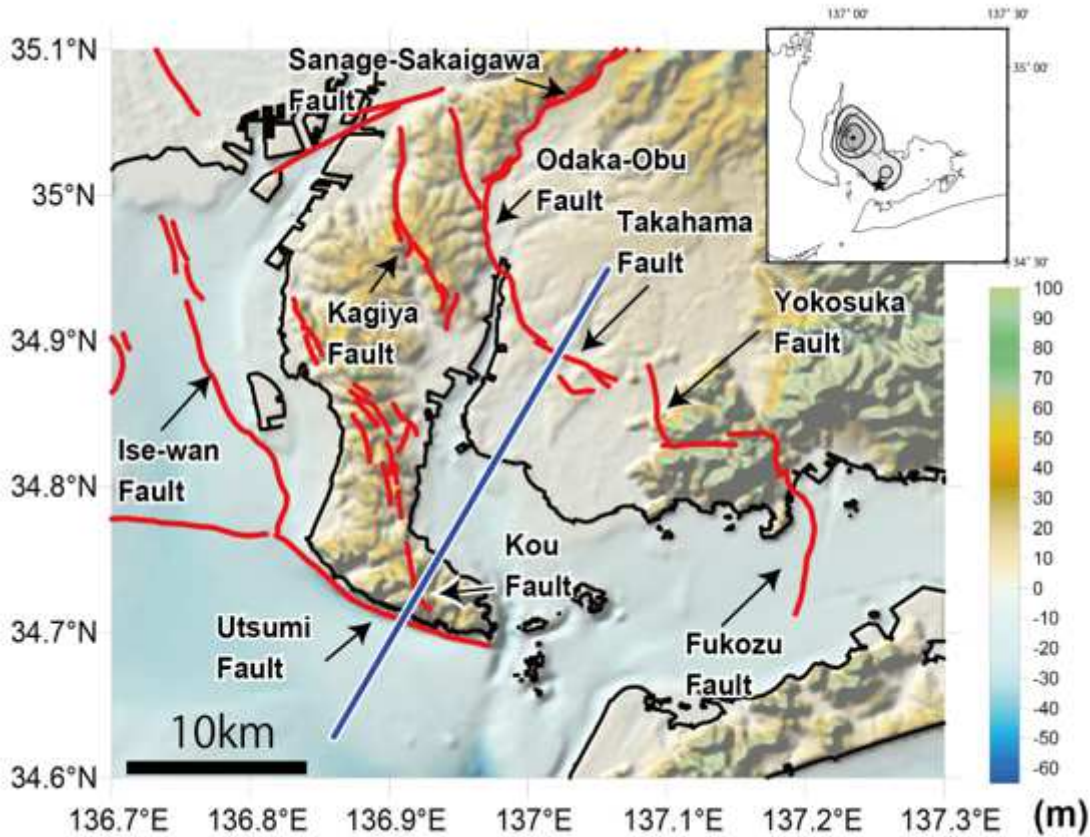

Figure 2

Topography and active faults in the Mikawa Bay Region. Red lines represent the traces of active faults in Figure 1(b) (National Institute of Advanced Industrial Science and Technology, 2020a). The blue line indicates the profile line shown in Figures 8, 9, and 10. The topography is illustrated using the 30 m gridded terrain data compiled by Murata et al. (2018). The top-right panel represents the slip distribution model of the 1945 Mikawa Earthquake (modified after Kikuchi et al., 2003). The increment of contour lines is 0.5 m and the star indicates the epicenter of the 1945 Mikawa Earthquake.
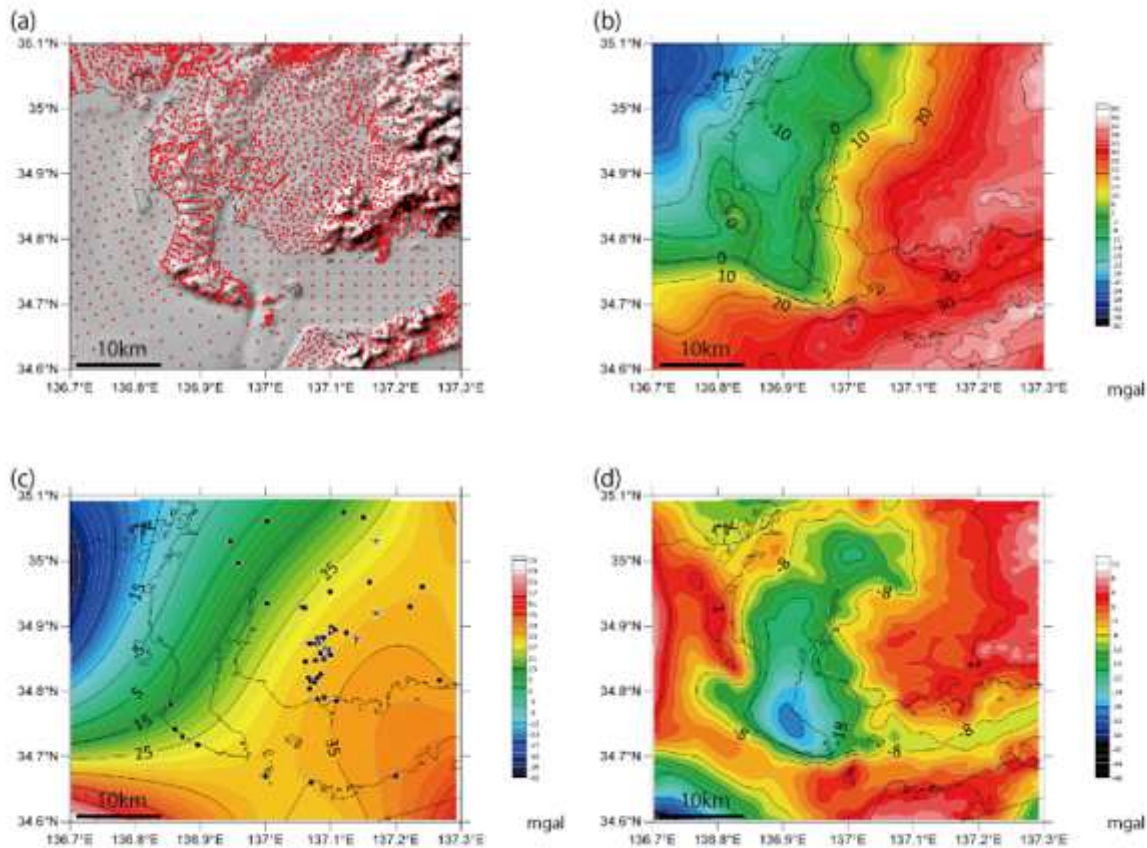

Figure 3

Bouguer anomaly of the study area. (a) Red dots indicate the location of gravity stations used for this analysis. (b) Bouguer anomaly calculated with a reduced density of 2.3 g/cm3. (c) Regional trend of the Bouguer anomaly. Black dots and crosses represent the boring locations and basement exposing locations, respectively. (d) Residual Bouguer anomaly obtained by deducting the regional trend (c) from the original Bouguer anomaly (b). The topography (a) is illustrated by using the 30 m gridded terrain data compiled by Murata et al. (2018).

$\Delta \rho = \rho_s - \rho_b$

Figure 4

Schematic diagrams showing the calculation of residual Bouguer anomalies at the boring sites and basement exposure points. (a) Definition of the elevation of points (h) and the density of the basement (ρ_b) and one unit of sediments/sedimentary rocks (ρ_s). The elevation of the buried basement surface is represented by H. (b) Gravitational corrections ( ) (Bouguer, free-air and terrain correction) are calculated using the density of the rock exposed at the observation points. gn is normal gravity in accordance with the Geodetic Reference System 1980 (GRS80). The corrected Bouguer anomaly (g_{BA}) represents the Bouguer anomaly considered. (c) The residual Bouguer anomaly (g') is obtained by removing the regional trend from the Bouguer anomaly (g_{BA}). The residual Bouguer anomaly must consist of the gravity

anomaly from the thickness of the sediments/sedimentary rocks (i.e., the elevation of the basement surface).

The figure shows a scatter plot with "Residual Bouguer anomaly (mgal)" on the y-axis (ranging from -20 to 5) and "Elevation of basement (m)" on the x-axis (ranging from -1500 to 500). Blue circles represent data points, and a red line fits the data. The red text annotation reads:

$$g = 0.0158H$$
$$\approx -2\pi G\,(-0.376)H$$
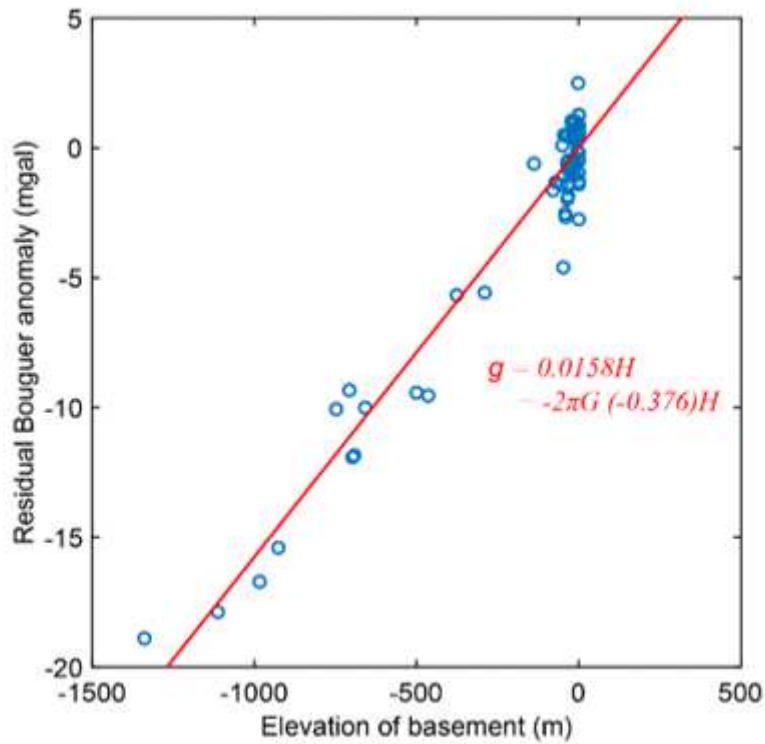

Figure 5

Relationship between the elevation of the basement and the residual Bouguer anomaly at the boring site or basement exposure (Fig. 4). The red line represents the relationship between the elevation of the basement and the residual Bouguer anomaly by using the least square method.
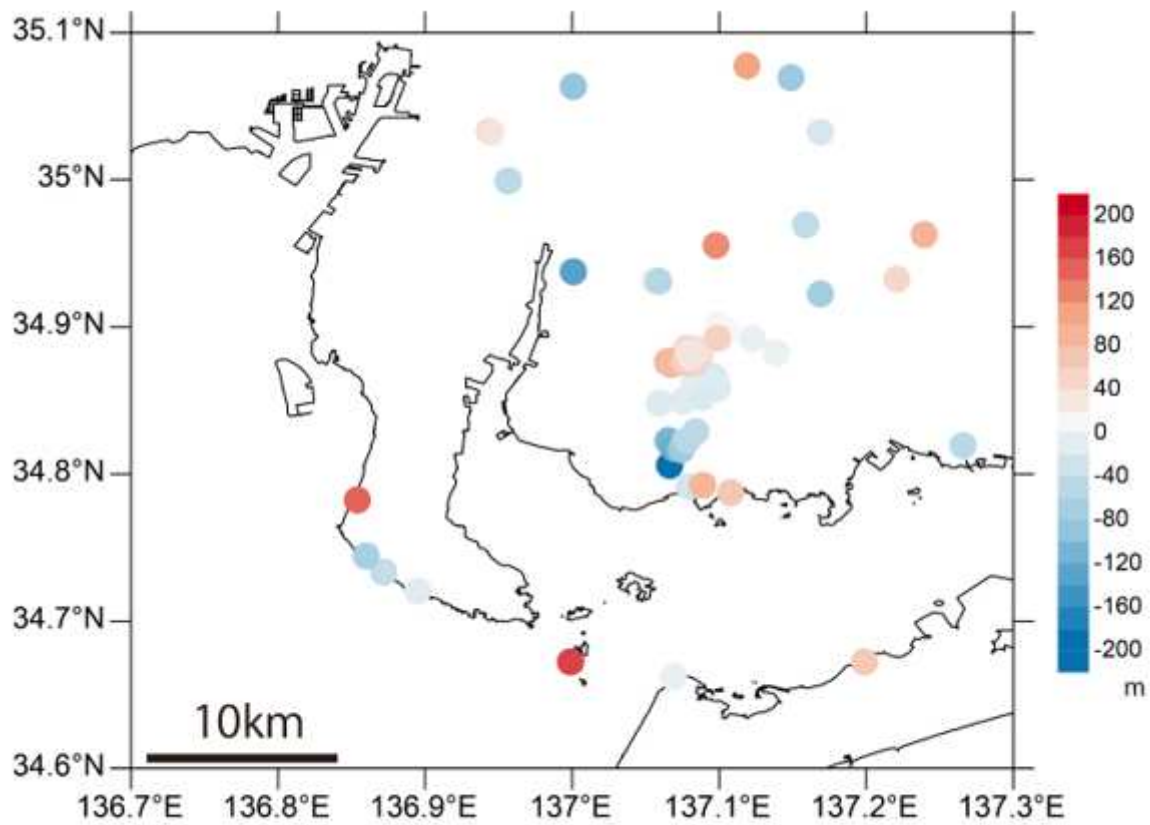

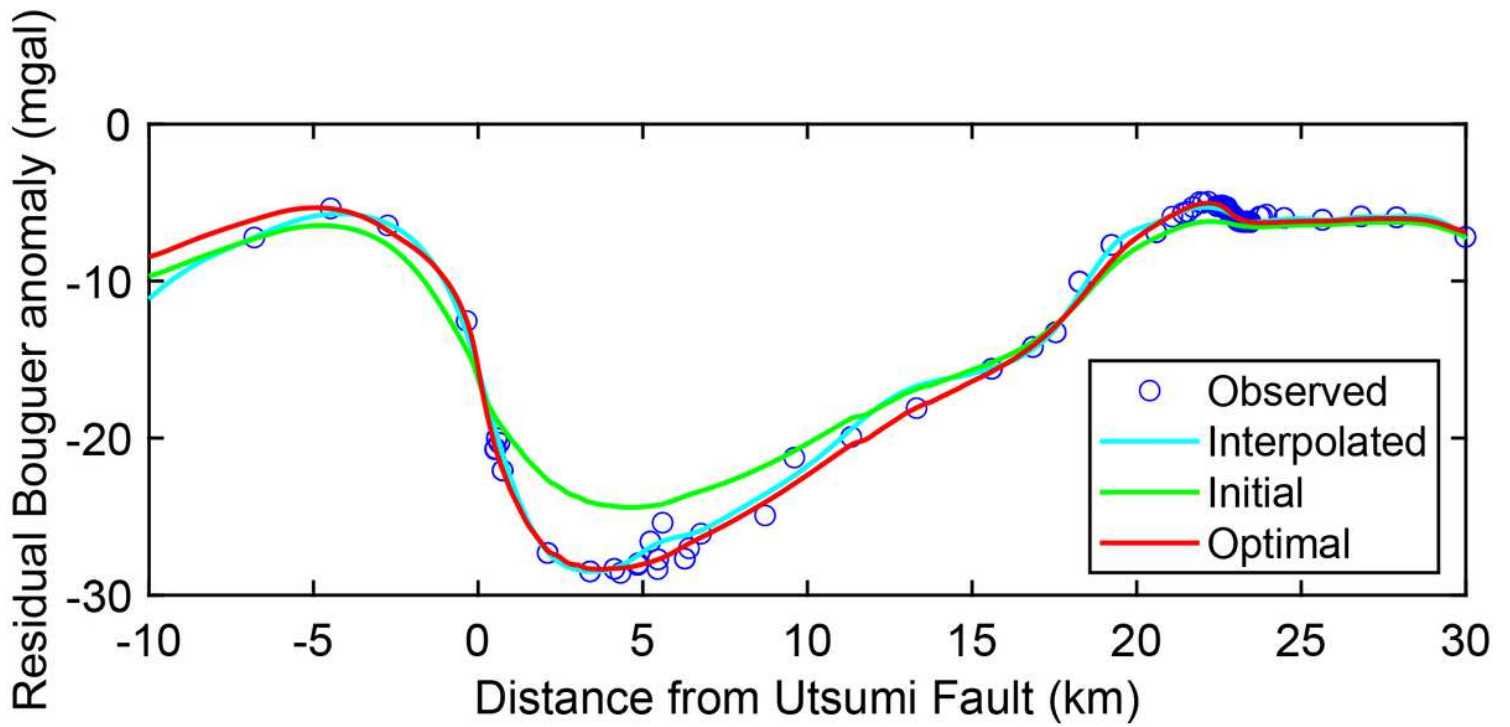

Figure 6

Difference between the observed elevation of the basement surface and the calculated elevation of the basement surface (see Fig. 5).
Figure 7

Gravity basement map obtained using the relationship between the depth of the basement and the residual Bouguer anomaly (Fig. 5) based on the the residual Bouguer anomaly map (Fig. 3d).
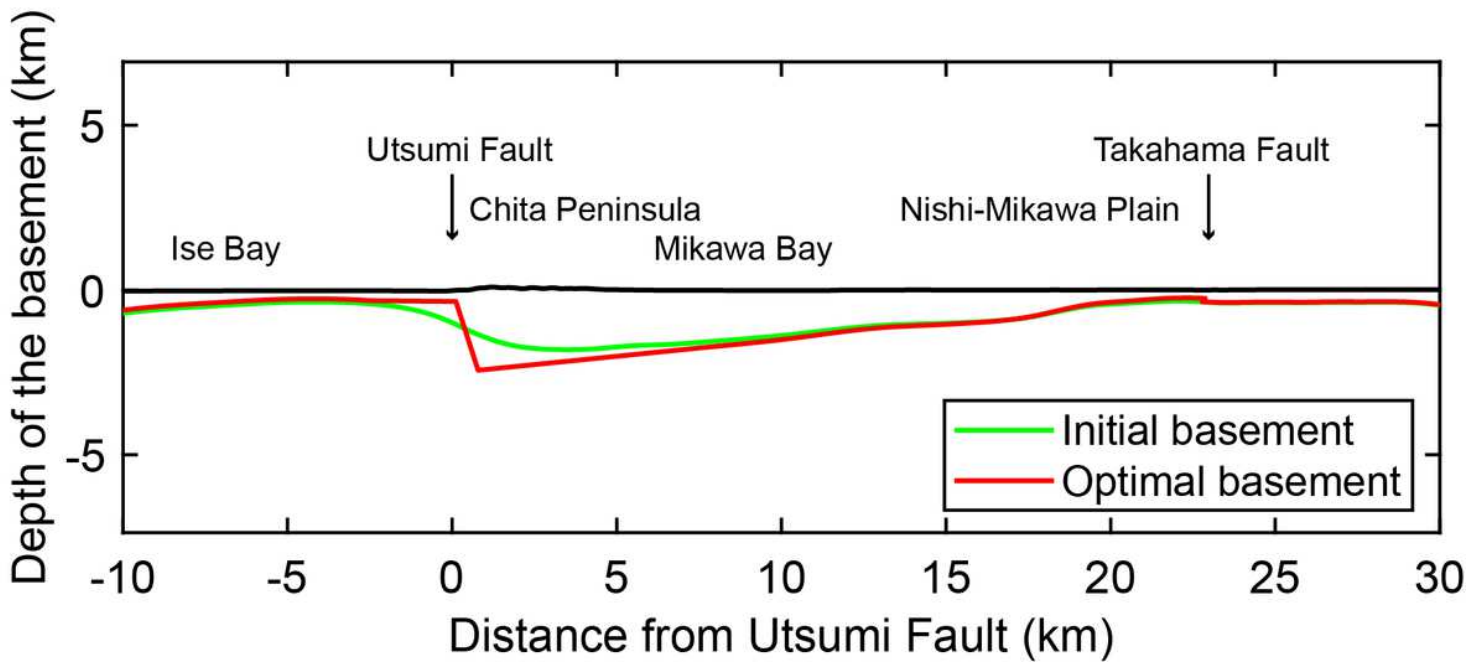

Figure 8

Profiles of the Bouguer anomaly (a) and the topography of the basement surface (b). (a) The observed and interpolated residual Bouguer anomalies are represented by the open circles and cyan line, respectively. The interpolated residual Bouguer anomalies come from that of the Fig. 3 (d). The green line and red line represent the calculated Bouguer anomaly from the initial model (green in b) and the optimum model (red in b) using the 2D Talwani's method. (b) The green line represents the initial model extracted from the gravity basement model (Fig. 5) along the survey line. The red line represents the

optimum basement model obtained by selecting the best parameters (see Table 2). The black line represents the elevation of the ground surface. The origin of the x-axis is set as the tip of the Utsumi Fault in both a and b.

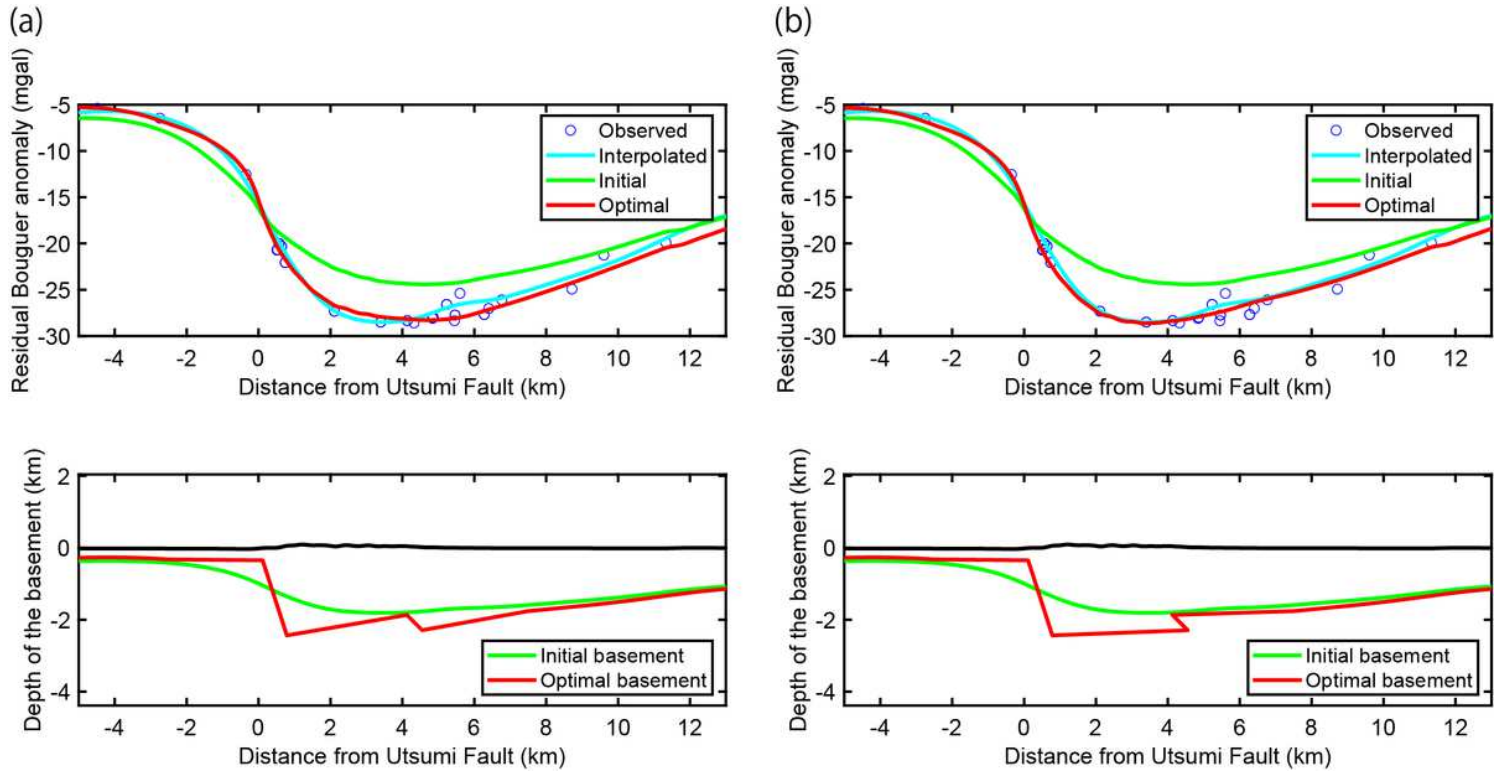

Figure 9

Close-up views of the profiles of the Bouguer anomaly (a) and the topography of the basement surface (b) around the Takahama Fault. The tip of the Takahama Fault is located at 22.98 km. (a) The observed and interpolated residual Bouguer anomalies are represented by open circles and the cyan line, respectively. The interpolated residual Bouguer anomalies come from that of the Fig. 3 (d). The green line

and red line represent the calculated Bouguer anomaly from the initial model (green in b) and the optimum model (red in b) using the 2D Talwani's method. (b) The green line represents the initial model extracted from the gravity basement model (Fig. 5) along the survey line. The red line represents the optimum basement model obtained by selecting the best parameters (Table 2). The black line represents the elevation of the ground surface. The origin of the x-axis is set at the tip of the Utsumi Fault in both a and b.

Figure 10

Profiles of the Bouguer anomaly and the topography of the basement surface with 600 m of displacement along the Kou Fault at 2.26 km with a dip of 45°E. (a) Reverse fault structure of the Kou Fault using the optimal basement model. (b) Normal fault structure of the Kou Fault using the optimal basement model. Lines and circles are same as shown in Figure 8. The origin of the x-axis is set at the tip of the Utsumi Fault in both a and b.

Figure 11

(a) Conceptual models for thrust faults developed by the dip-slip inversion of a normal fault system (modified after McClay and Buchanan, 1992). The white arrow represents normal faulting during the extensional stage. Black arrows indicate reverse faulting during the compressional stage following the extensional stage. (b) Conceptual models for the fault system across the Chita Peninsula and the Nishi–Mikawa Plain (not to scale). The white arrow represents the normal faulting in the extensional stage in Miocene. Black arrows indicate reverse faulting during the compressional stage following extensional stage in the Pliocene to Quaternary.
