Abstract:

Spatially compound extremes pose substantial threats to globally interconnected social-economic systems. We use an Earth system model large ensemble to examine the future risk of compound droughts during the boreal summer over ten global regions with highly seasonal climate. Relative to the late-20th century, the probability, mean extent and severity of compound droughts increase by ~60%, ~10% and ~20% respectively by the late-21st century, with a disproportionate increase in risk across North America and the Amazon. These changes result in a ~9-fold increase in exposure over agricultural areas and ~5 to 20-fold increase in population exposure depending on the shared socioeconomic pathway. ENSO is the predominant large-scale driver of compound droughts with 68% of historical events occurring during El Niño or La Niña conditions. ENSO teleconnections remain

32 **stationary in the future though an ~22% increase in ENSO extremes combined with**
33 **projected warming, drive the elevated risk of compound droughts.**
34
35

36 Spatially and/or temporally compounding Earth system extremes can lead to cascading impacts
37 on global socio-economic systems¹⁻⁶. Several recent studies have examined temporally
38 compounding events resulting from different combinations of climatic hazards occurring in the
39 same location at the same time, such as hot and dry conditions^{7,8} or heavy precipitation and
40 extreme winds⁹. The simultaneous occurrence of extremes across multiple regions, referred to as
41 spatially compound extremes, have received relatively limited attention. Spatially compound
42 extremes have the potential to accumulate hazard impacts in distant locations and pose
43 amplifying pressures on a network of interconnected socioeconomic systems^{1,10-15}. For example,
44 severe droughts that concurrently occurred across Asia, Brazil, and Africa during 1876 to 1878
45 led to synchronous crop failures, followed by famines that killed more than 50 million people in
46 those regions¹⁶. The complex and interconnected nature of the current global food network
47 makes agricultural shocks, even over a few individual regions, capable of having ripple effects
48 on global food prices and food security, particularly in socioeconomically vulnerable regions^{11,17}.
49 Compound extremes can also influence global economies through their impacts on international
50 agribusiness and reinsurance industries^{7,18,19}. Therefore, understanding the drivers of
51 simultaneous extremes across regions and the exposure of human systems to such extremes can
52 inform assessments of the climate risks to interconnected systems and planning for their societal
53 impacts.

54 Recent studies have examined the risk of crop failures from compound extremes and highlighted
55 various physical drivers and mechanisms. The risk of multiple-breadbasket failures is elevated
56 during the simultaneous physical hazards imposed by the large-scale natural climate variability
57 modes such as El Niño-Southern Oscillation (ENSO), Indian Ocean Dipole, and Atlantic
58 Niño^{12,13,20}. ENSO is one of the predominant drivers of hydroclimate variability across tropical
59 regions, as El Niño events are associated with several major synchronous historical droughts
60 across Asia, Africa and South America^{16,21}. For instance, the strong El Niño event in 1983
61 caused extreme heatwaves and droughts across multiple maize-producing regions that resulted in
62 the most extensive simultaneous crop failures in recent records^{13,17}. Overall, ~80% of historical
63 compound droughts over tropical/subtropical belt are associated with El Niño conditions during
64 the boreal summer²⁰. Projected anthropogenic warming is expected to double the risk of
65 concurrent hot and dry extremes over certain croplands and pastures⁷ and enhance the risk of
66 globally synchronized shocks on temperature-sensitive crops such as Maize¹⁵, highlighting the
67 importance of understanding the drivers of compounding stressors.

68 This study aims to understand future changes in the characteristics and drivers of spatially
69 compounding droughts (hereafter compound droughts) that could result in simultaneous shocks
70 across multiple regions, highlighting the increasing risks to a suite of climate-sensitive sectors
71 and systems. Our analysis focuses on ten tropical and subtropical regions, defined in the
72 Intergovernmental Panel on Climate Change (IPCC) Special Report on Managing the Risks of
73 Extreme Events and Disasters to Advance Climate Change Adaptation (SREX), that exhibit high
74 variability in summer precipitation and receive a large fraction of their annual precipitation
75 during their summer season. Several of these regions exhibit similar socioeconomic and climate
76 characteristics, including areas where rainy seasons and agricultural production are strongly

77 influenced by the global monsoon systems. These regions also include important breadbaskets
78 and vulnerable populations that depend on rainfed agriculture for their livelihood^{22,23}. Given the
79 importance of ENSO for hydroclimate variability over many of these regions^{13,16,24-27}, we
80 investigate the influence of El Niño and La Niña events on compound drought characteristics in
81 the historical and future climates. We also quantify changes in the population and agricultural
82 land exposure to compound droughts to understand societal implications of projected changes.

83

84 **Historical and future characteristics of compound droughts.** We find significant increases in
85 the frequency, spatial extent, and average intensity of compound droughts in the late-21st century
86 (2071–2100) relative to the late 20th century (1971–2000) in the Community Earth System Model
87 Large Ensemble simulations for the high-emissions Representative Concentration Pathway 8.5
88 (Figure 1). The number of regions simultaneously under drought is significantly (p -value <0.05)
89 higher in the future relative to the historical climate (Figure 1b), contributing to a ~60% increase
90 in the probability of compound droughts (historical probability = 0.32 and future probability =
91 0.51). The fraction of drought-affected area during compound droughts is also significantly
92 higher in the future climate, with the probability of widespread compound droughts increasing by
93 ~30% relative to the historical climate (Figure 1c). Likewise, the mean severity of compound
94 droughts also increases (Figure 1d) along with the probability of severe compound droughts,
95 which increases ~6-fold from 0.12 in the historical climate to 0.75 in the future climate. As a
96 result, nearly 3 out of 4 compound droughts in the future are classified as severe (Figure 1d).

97 We quantify the impacts of more frequent, extensive and severe compound droughts on
98 agricultural land (the combination of cropland and pastureland) and population by calculating
99 changes in their exposures to compound droughts (Figure 2). These exposures exhibit distinct
100 differences between the two climates and are sensitive to drought severity. While agriculture
101 areas exposed to moderate compound droughts in the historical climate is twice as high as in the
102 future climate (Figure 2a), their exposure to severe compound droughts increases ~10-fold in the
103 future climate. An average of ~0.7 million km² of agricultural land is likely to be exposed to
104 severe compound droughts every year in the future climate compared to ~0.07 million km² in the
105 historical climate (Figure 2a). Since the agricultural area does not change in the two analyses
106 periods, the differences in exposure is largely driven by changes in the frequencies and extent of
107 moderate and severe compound drought in the two time periods.

108 Increases in the severity of compound droughts in future climate is associated with changes in
109 the characteristics of the water cycle. Specifically, several regions either exhibit a decrease in
110 precipitation (CNA, CAM, and northern AMZ), or an increase in ET (northern CAM and ENA),
111 both of which enhance surface drying (Figure S1c,d) and elevate the risk of compound droughts
112 (Figure S2a). As a result, there is an increase in the likelihood of severe compound droughts
113 exposure to agricultural lands within these regions (Figure 3a,b; Figure S2a,b). Alternatively, the
114 decrease in agricultural exposure to moderate compound droughts over the EAS, SAS and EAF
115 regions is due to an increase in summer precipitation in the future climate (Figure S1; Figure 3b).
116 As a result, these regions are less likely to experience compound droughts in the future climate
117 (Figure 3a). Although a reduction in agricultural exposure to compound droughts is projected
118 over EAF, there is a considerable uncertainty in the response of EAF precipitation to warming²⁸.

119 Differences in the distribution and growth of population in the five Shared Socioeconomic
120 Pathways (SSPs) lead to substantially varying population exposures to compound droughts

121 (Figure 2b). Future population exposure to severe (moderate) compound droughts increases
122 (declines) under all SSPs (Figure 2b). In the historical climate, an average of ~10 million people
123 are at risk of experiencing severe compound droughts every year, which increases to an average
124 of ~120 million people under SSP1 and SSP5, ~160 million under SSP2 and SSP4, and more
125 than 210 million people under SSP3 every year by the late 21st century (Figure 2b). The
126 exceptionally large increase in population exposure to severe compound droughts under SSP3 is
127 primarily driven by a large increase in the frequency of severe compound droughts and in the
128 population across all regions except SEA and EAS (Figure 3c; Figure S2c-f). Despite declines in
129 compound droughts risk, the projected increase in population over EAF, WAF, and SAS
130 contributes to increasing future population exposure²⁹ (Figure 3a).

131 **Physical drivers of compound droughts.** ENSO is the dominant mode of natural climate
132 variability influencing compound droughts in the boreal summer season (Figure 4)^{16,20}.
133 Historically, ~68% of compound droughts are associated with significant ENSO events, of which
134 El Niño conditions alone account for ~46% of compound droughts occurrences (Figure 4b). With
135 the projected warming, ENSO events become more frequent, including a 30% increase in El
136 Niño and 15% increase in La Niña conditions (Figure 4a). The more frequent occurrences of
137 ENSO in the future warmer climate are consistent with previous studies^{30,31}. In the future
138 climate, ~75% of compound droughts are driven by ENSO variability, and the fraction of
139 compound droughts associated with El Niño conditions increases to ~50% (Figure 4b). In total,
140 compound droughts events associated with El Niño and La Niña conditions increase by ~70%,
141 from 263 events in the historical climate to 448 in the future climate, in response to a ~22%
142 future increase (from 712 to 869 events) in the frequency of ENSO events (Figure 4a, b). The
143 frequency of compound droughts associated with non-ENSO drivers also exhibit a moderate
144 increase of ~25% (Figure 4b). The proportional occurrence of compound droughts during El
145 Niño and La Niña conditions is similar in both time periods (i.e., association with El Niño is ~2
146 (1.96) times more than La Niña in the historical (future) climate) (Figures 4b). Collectively,
147 these characteristics of future changes not only manifest as a stronger role of ENSO in driving
148 summer season compound droughts, but also suggest that ENSO teleconnections over the study
149 regions remain largely stationary.

150 The more prominent role of El Niño in driving spatially compound droughts is due to its negative
151 correlation with precipitation variability over most of the studied regions. El Niño conditions
152 lead to intense and widespread drying over CAM, AMZ, WAF, EAF, EAS, southern SAS, and
153 SEA in the historical climate (Figure S3a). In contrast, La Niña conditions lead to drying over
154 relatively fewer studied regions, including CNA, ENA, southern WAF, and northern SEA
155 (Figure S3c). El Niño-driven compound droughts also exhibit relatively larger mean drought
156 extent compared to La Niña-driven compound droughts in both climates, and compared to non-
157 ENSO driven compound droughts in the historical climate (Figure 5a-c). While La Niña-driven
158 compound droughts events exhibit higher intensity in the historical climate, more intense
159 compound droughts are predominantly due to El Niño conditions in the late 21st century (Figure
160 5c). In fact, El Niño-driven compound droughts not only have the highest mean severity in the
161 future climate, but their extreme severity is also the highest among all the drivers (Figure 5c).
162 These changes are consistent with relatively strong future climate drying during El Niño
163 conditions (Figure S3). The composites of Standardized Precipitation Evapotranspiration Index
164 (SPEI) during El Niño show an expansion of the drought area over AMZ and CAM, and an
165 intensification of dry conditions over EAF and SEA in the future climate. Some intensification of

166 drying is also present during La Niña (non-ENSO) conditions over ENA, WAF and AMZ (CAM
167 and AMZ) in the future climate (Figure S3c-f).

168

169 **ENSO Teleconnections.** We investigate changes in the influence of ENSO over the study
170 regions by examining its teleconnections with SPEI (Figure 6) and precipitation anomalies across
171 the study regions (Figure S4). The magnitude and pattern of correlations between the summer
172 ENSO index and the SPEI/precipitation is very similar in both time periods, which highlights the
173 fact that the ENSO teleconnections over most regions remain largely stable with the exception of
174 ENA, WAF and EAF where correlations are stronger in the future climate (Figure 6a-b,d, S4).
175 The area with a significant correlation between SPEI and ENSO over ENA increases from ~40%
176 in the historical climate to ~70% in the climate (Figure 6c). Moreover, the average correlation
177 over WAF (EAF) increases to ~0.35 (~0.4) in future climate relative to ~0.25 (~0.35) in the
178 historical climate (Figure 6d). Corresponding to the relative strengthening of ENSO
179 teleconnections, the SPEI composite shows stronger dry conditions over western EAF during El
180 Niño conditions and over southern WAF and eastern ENA during La Niña conditions in the
181 future climate (Figure S5). Similarly, wet conditions also exhibit strengthening over southern
182 WAF and eastern ENA during El Niño, and over eastern EAF during La Niña conditions (Figure
183 S4). Broadly, the nature of ENSO teleconnections remain stationary in the future climate, which
184 highlights the importance of understanding the current ENSO-compound droughts relationship
185 and their related physical processes²⁰.

186

187 **Discussion.** Droughts are associated with a range of environmental, economic, and social
188 impacts. Given the increasing global connectivity of socio-economic systems, understanding the
189 historical characteristics of compound droughts and anticipating their changes in a future warmer
190 climate is important for a broad suite of interconnected, climate-sensitive sectors⁷. The
191 agricultural sector, in particular, is highly sensitive to simultaneous shocks across multiple
192 regions because of the complex networks of food supply, demand and global trade⁶. The
193 projected increase in agricultural exposure to compound droughts highlights the higher
194 likelihood of simultaneous production shocks across multiple breadbaskets in the future period
195 that could affect global food availability and security. Our results indicate that the North and
196 South American regions, considered in this study, are more likely to experience compound
197 droughts in a future warmer climate as compared to the regions in Asia and Africa, where much
198 of the areas affected by monsoons are projected to become wetter³². The contribution of food
199 produced within the Americas to the global food system could, therefore, be more susceptible to
200 such climatic hazards. For instance, the United States is a major exporter of staple grains and
201 currently exports maize (soyabean) to >160 (>90) countries across the globe^{11,33}. Therefore, a
202 modest increase in the risk of compound droughts in the future climate can lead to regional
203 supply shortfalls that could cascade into the global market, affecting global prices and
204 amplifying food insecurity. Additionally, our results have broader implications for the global
205 virtual water trade network involved in the water-intensive agricultural, forestry, industrial, and
206 mining products^{34,35}. In last three decades, international trade of virtual water has tripled³⁵ and is
207 expected to increase further in response to increases in population and demand by end of 21st
208 century³⁶. Therefore, the projected increases in the frequency and severity of compound droughts
209 could disrupt the supply-demand network of such water intensive goods and thereby, can affect
210 their availability and prices in global market.

211 In addition to impacts on such connected systems, the interplay of projected growth in
212 population and changes in compound drought characteristics will also exacerbate direct
213 population exposure to drought impacts. The largest increase in population exposure to severe
214 compound droughts is projected under SSP3, which represents a fragmented future world of
215 resurgent nationalism, low-income growth, focus on domestic or regional issues, and high
216 population growth in developing countries²⁹. Persistent inequality and low economic growth
217 under SSP3 indicate societies that are likely less resilient to severe compound droughts and
218 consequently might experience higher socio-economic impacts. In contrast, the increase in
219 population exposure to compound drought is lowest under SSP1. SSP1 represents a trajectory
220 of sustainable development, lower inequality, high economic growth, higher investment in
221 human capital and a focus on global commons²⁹, which might be better prepared to manage the
222 impacts of compound droughts. Irrespective of the scenario, a warming climate will amplify
223 stresses on international agencies responsible for disaster relief by requiring the provision of
224 humanitarian aid to a greater number of people simultaneously exposed to drought-related
225 disasters.

226 Efforts to better understand and constrain the hydroclimatic impacts of ENSO variability,
227 however, can support predictability and management of compound drought impacts in a warmer
228 climate. Our findings suggest that the regional teleconnections during El Nino or La Nina
229 conditions do not change substantially, with increases mainly in the intensity of compound
230 droughts in the future climate relative to historical climate. These results imply that when ENSO
231 events occur, they will likely affect the same geographical regions albeit with greater severity.
232 The occurrence of nearly 75% of compound droughts with ENSO events in the future climate
233 highlights the potential for predictability of compound droughts and their impact at lead times of
234 up to 9-months³⁷. Timely predictions of compound droughts and their impacts on agricultural
235 areas and communities can facilitate international agribusiness industries to minimize the
236 economic losses and insurance and re-insurance industries to design effective insurance schemes
237 to reduce losses from simultaneous disasters.

322

323 **Methods**

324 **Datasets.** We use the 40-member Community Earth System Model Version-1 (CESM1) Large
325 Ensemble Simulations (LENS) to examine the drivers of historical (1971-2000) compounding
326 droughts and their projected changes (2071-2100) under the RCP8.5 scenario³⁸. Each ensemble
327 member of the CESM-LENS differs only in its initial atmospheric conditions and has identical
328 external forcing, thereby providing an opportunity to investigate the influence of internal
329 variability under different climate conditions. CESM demonstrates high skill in reproducing the
330 observed global precipitation patterns, ENSO characteristics (e.g., intensity, frequency and
331 related global teleconnections)^{30,31,39}..

332 We use observed monthly precipitation data for 1981–2019 from the Climate Hazards Group
333 Infrared Precipitation with Stations (CHIRPS) version 2⁴⁰ to estimate the Shannon Entropy
334 index⁴¹, which is used to identify the regions of high variability in the summer precipitation.
335 CHIRPS combines satellite-based precipitation estimates with in-situ observations and models of
336 terrain-based precipitation to provide spatially fine and continuous data⁴⁰. For the calculation of
337 changes in population and agricultural land exposures, historical (for the year 2000) and
338 projected future population (for the year 2100) at 1-km spatial resolution⁴² <
339 [https://sedac.ciesin.columbia.edu/data/set/popdynamics-1-km-downscaled-pop-base-year-](https://sedac.ciesin.columbia.edu/data/set/popdynamics-1-km-downscaled-pop-base-year-projection-ssp-2000-2100-rev01)
340 [projection-ssp-2000-2100-rev01](https://sedac.ciesin.columbia.edu/data/set/popdynamics-1-km-downscaled-pop-base-year-projection-ssp-2000-2100-rev01)>, and crop and pastureland fraction (based on the year 2000)
341 <<https://sedac.ciesin.columbia.edu/data/set/aglands-pastures-2000>> at 10-km spatial resolution⁴³
342 are obtained from the NASA Socioeconomic Data and Applications Center. We consider the
343 population projections from all five Shared Socioeconomic Pathways (SSPs) to quantify the
344 uncertainty in population exposure to compounding droughts under projected future warming.

345

346 **Selection of Regions.** We quantify compound droughts across 10 SREX regions: Amazon
347 (AMZ), Central America (CAM), Central North America (CNA), East Africa (EAF), East Asia
348 (EAS), East North America (ENA), South Asia (SAS), Southeast Asia (SEA), Tibetan Plateau
349 (TIB), and West Africa (WAF). We consider these regions for the following reasons: (1) many
350 of these regions are connected by the global summer monsoon systems and influenced by similar
351 large-scale modes of variability²⁷, (2) these receive the largest fraction of annual precipitation
352 during the summer season (June – September; JJAS)^{22,27} and exhibit strong variability in summer
353 precipitation, and (3) these include several major breadbaskets and populations vulnerable to
354 climate variability and change²³.

355 To identify the sub-regions that exhibit high variability in summer precipitation, we estimate the
356 observed Shannon Entropy Index⁴¹ using monthly summer precipitation from the CHIRPS
357 dataset. We only consider those regions that show high variability (entropy >4.86; median
358 entropy values across the areas studied) in the monthly summer precipitation over at least 30% of
359 their total area (Figure 1a). The Shannon Entropy H is estimated using the following equation⁴⁴,

360

$$361 \quad H = -\sum p_i \log_2 p_i \quad (1)$$

362

363 where, p is the probability of each i^{th} value of the time series. The areas within each region that
364 satisfy the Shannon entropy criterion compare well between observations (CHIRPS) and
365 simulations (CESM) (Figures 1a, S6). The only exception is over AMZ where the extent of
366 simulated area with high variability is relatively smaller than observed (Figure S6). Furthermore,
367 CESM exhibits skills in simulating the compound droughts characteristics across these regions
368 that have been described in Singh *et al*²⁰.

369

370 **Drought Characteristics.** We use Standardized Precipitation Evapotranspiration Index (SPEI)
371 to define drought^{45,46}. SPEI is estimated using a simple climatic water balance, i.e., the difference
372 between the accumulated summer season precipitation and evapotranspiration (ET)⁴⁵. We
373 compute ET as the sum of ground and canopy evaporation and transpiration for the present and
374 future climates from CESM-LENS following the approach provided by Mankin *et al*⁴⁷. To

375 construct SPEI, we follow a procedure similar to the Standardized Precipitation Index
 376 calculations proposed by McKee *et al*⁴⁸. We use a log-Logistic distribution to estimate the
 377 probability distribution of P-ET instead of the Gamma distribution⁴⁵ that is used for SPI⁴⁹. The
 378 gamma distribution requires a variable with non-negative values, which makes it inappropriate
 379 for SPEI estimation because the P-ET may yield negative values. Hence, we estimate the
 380 probability of P-ET based on the widely used two-parameter Log-logistic distribution and then
 381 transform it to a standard normal distribution to make it comparable across space and time^{45,46}.
 382 Future (2071–2100) SPEI calculations use historical (1971–2000) climate characteristics to
 383 characterize changes in compound droughts relative to the historical climate.

384 We use the threshold of -1σ of the historical SPEI to classify a grid cell experiencing drought ($<-$
 385 1σ) in the historical and future climates. We define an individual drought over a region if the
 386 fractional area experiencing drought conditions ($\text{SPEI} < -1\sigma$) exceeds the 80th percentile of the
 387 historical long-term average drought area. A compound droughts event is identified if at least
 388 three of the ten SREX regions concurrently experience drought. Compound drought area is
 389 defined as the fraction of the total area across the regions involved in compound droughts events.
 390 Similarly, the compound droughts intensity is computed as average SPEI over drought-affected
 391 areas across those regions. A compound drought event is classified as widespread when the
 392 drought-affected area exceeds the 90th percentile of the historical long-term average area affected
 393 by compound droughts (i.e. $\sim 41\%$). Furthermore, these events are classified as severe (moderate)
 394 when average SPEI across all drought-affected areas is below (above) the 10th percentile (\sim
 395 -1.65) of the historical long-term average SPEI over drought-affected areas during compound
 396 droughts.

397

398 **Crop, pasture lands and population exposure.** There is a mismatch between the horizontal
 399 grid spacing of climate data and cropland, pastureland and population datasets. Moreover, the
 400 rate of population growth varies across space and depends on several local and global spatial
 401 interactions²⁹. Therefore, it is not appropriate to use interpolation methods to upscale the
 402 population data to match $\sim 1^\circ$ CESM grid cells. Therefore, instead of remapping, we aggregate
 403 the population across the grid cells (at 1 km spatial resolution) that fall inside the $\sim 1^\circ$ CESM grid
 404 cells to calculate population exposure. We follow same procedure for crop and pasture lands.
 405 Given the importance of cropland for food cultivation and pastureland for animals grazing, we
 406 quantify the exposure of these land types to compound droughts. Cropland, pastureland and
 407 population exposures are calculated as follows:

$$408 \quad \text{Cropland and pastureland exposure: } \frac{1}{N} \sum_{i=1}^n a_i \quad (1)$$

409

410 where, N is number of years, i indicates years with compound droughts events, a indicates the
 411 total drought affected cropland or pastureland across the regions involved in the compound
 412 droughts. Cropland and pastureland is based on the year 2000 and is fixed for both present and
 413 future climates.

414

$$415 \quad \text{Population exposure: } \frac{1}{N} \sum_{i=1}^n p_i \quad (2)$$

416

417 Where, N is number of years, i indicates years with compound drought, p indicates the number of
418 people experiencing drought across the regions involved in the compound droughts. We consider
419 historical population based on year 2000 and projected future population based on year 2100
420 under all five SSPs.

421

422 **Large-scale Modes of Variability.** We define the ENSO index using the average summer (June
423 to September; JJAS) sea surface temperatures anomalies (SSTA) over the Niño3.4 region (5S-
424 5N, 170W-120W)⁵⁰. We remove the forced climate change component from each member of the
425 large ensemble by subtracting the time-varying mean of all ensemble members, as follows:

$$426 \quad SSTA_{i,j} = SST_{i,j} - \left(\frac{1}{40} \sum_{j=1}^{j=40} SST_j\right)_i \quad (3)$$

427

428 where i represents the year and j represents the ensemble member. El Niño and La Niña are
429 defined as exceedances of $\pm 0.5\sigma$, where the standard deviation (σ) is estimated using the
430 historical ENSO index values (1971–2000)²⁰.

431 **Statistical Significance of the changes in compound droughts.** We employ the non-parametric
432 permutation test to assess the statistical significance of the differences in mean compound
433 droughts characteristics in the historical and future climates⁵¹. We first quantify the test statistic
434 (i.e. difference in the means of the distributions of compound droughts characteristics) from the
435 two original historical and future distributions and then estimate an empirical distribution of the
436 test statistic by randomly permuting the samples from the two distributions and re-estimating the
437 test statistic from the resampled distributions, 10,000 times. If the original test statistic is higher
438 (lower) than the 95th (5th) percentile of the empirical distribution, we consider the mean of
439 compound droughts characteristics between historical and future climates to be significantly
440 different at the 5 percent significance level.

441 **Data availability**

442 All datasets used in the manuscript are publicly available and their sources are provided in the
443 “Methods” section.

444 **Code availability**

445 The scripts developed to analyze these datasets can be made available on request from the
446 corresponding author.
