Abstract

In single-cell RNA-sequencing (scRNA-seq), gene expression is assessed individually for each cell, allowing the investigation of developmental processes, such as embryogenesis and cellular differentiation and regeneration, at unprecedented resolutions. In such dynamic biological systems, grouping cells into discrete groups is not reflective of the biology. Cellular states rather form a continuum, e.g., for the differentiation of stem cells into mature cell types. This process is often represented via a trajectory in a reduced-dimensional representation of the scRNA-seq dataset.

While many methods have been suggested for trajectory inference, it is often unclear how to handle multiple biological groups or conditions, e.g., inferring and comparing the differentiation trajectories of wild-type and knock-out stem cell populations.

In this manuscript, we present a method for the estimation and downstream interpretation of cell trajectories across multiple conditions. Our framework allows the interpretation of differences between conditions at the trajectory, cell population, and gene expression levels. We start by integrating datasets from multiple conditions into a single trajectory. By comparing the conditions along the trajectory's path, we can detect large-scale changes, indicative of differential progression. We also demonstrate how to detect subtler changes by finding genes that exhibit different behaviors between these conditions along a differentiation path.

The emergence of RNA sequencing at the single-cell level (scRNA-Seq) has enabled a new degree of resolution in the study of cellular processes. The ability to consider biological processes as continuous phenomena instead of individual discrete stages has permitted a finer and more comprehensive understanding of dynamic processes such as embryogenesis and cellular differentiation. Trajectory inference was one of the first applications that leveraged this continuum [1] and a consequential number of methods have been proposed since then [2–4]. Saelens et al. [5] offer an extensive overview and comparison of such methods. Analysis of scRNA-Seq datasets using a curated database reveals that about half of all datasets were used for trajectory inference (TI) [6]. At its core, TI represents a dynamic process as a directed graph. Distinct paths along this graph are called lineages. Individual cells are then projected onto these lineages and the distance along each path is called pseudotime. In this setting, developmental processes are often represented in a tree structure, while cell cycles are represented as a loop. Following TI, other methods have been proposed to investigate differential expression (DE) along or between lineages, either as parts of TI methods [3, 7] or as separate modules that can be combined to create a full pipeline [8].

More recently, other methods have emerged to answer an orthogonal problem, focusing on systems under multiple conditions. This includes, for example, situations where a biological process is studied both under a normal (or control) condition and under an intervention such as a treatment [9–11] or a genetic modification [12]. In other instances, one may want to contrast healthy versus diseased [13] cells or even more than two conditions [14]. In such settings, one might look for differential abundance, i.e.,

40 cell population shifts between conditions. Initial analytical approaches ignored the continuous nature of
 41 biological processes and binned cells into discrete clusters before looking at differences in composition
 42 between clusters. Borrowing from the field of mass cytometry [15], *milo* [16], and *DAseq* [17] rely on
 43 low-dimensional representations of the observations and define data-driven local neighborhoods in which
 44 they test for differences in compositions. Each of these methods show clear improvements in performance
 45 over cluster-based methods, and provide a more principled approach that better reflects the nature of
 46 the system.

47 However, many studies with multiple conditions, if not most, actually involve processes that can be
 48 described by a trajectory. Utilizing this underlying biology could increase either the interpretability of
 49 the results or the ability to detect true and meaningful changes between conditions. In this manuscript,
 50 we present the **condiments** workflow, a general framework to analyze dynamic processes under multiple
 51 conditions that leverages the concept of a trajectory structure. **condiments** has a more specific focus
 52 than *milo* or *DAseq*, but it compensates for this by improving the quality of the differential abundance
 53 assessment and its biological interpretation. Our proposed analysis workflow is divided into three steps.
 54 In Step 1, **condiments** considers the trajectory inference question, assessing whether the dynamic process
 55 is fundamentally different between conditions, which we call *differential topology*. In Step 2, it tests
 56 for differential abundance of the different conditions along lineages and between lineages, which we
 57 respectively call *differential progression* and *differential differentiation*. Lastly, in Step 3, it estimates
 58 gene expression profiles similarly to Van den Berge et al. [8] and tests whether gene expression patterns
 59 differ between conditions along lineages, therefore extending the scope of **differential expression**.

60 In this manuscript, we first present the **condiments** workflow, by detailing the underlying statistical
 61 model, and providing an explanation and intuition for each step. We then benchmark **condiments** against
 62 more general methods that test for differential abundance to showcase how leveraging the existence of a
 63 trajectory improves the assessment of differential abundance. Finally, we demonstrate the flexibility and
 64 improved interpretability of the **condiments** workflow in three case studies that span a variety of biological
 65 settings and topologies.

66 Results

67 General model and workflow

68 **Data structure and statistical model.** We observe gene expression measures for J genes in n cells,
 69 resulting in a $J \times n$ count matrix \mathbf{Y} . For each cell i , we also know its condition label $c(i) \in \{1, \dots, C\}$
 70 (e.g., “treatment” or “control”, “knock-out” or “wild-type”). We assume that, for each condition c , there
 71 is an underlying developmental structure \mathcal{T}_c , or trajectory, that possesses a set of L_c lineages.

72 For a given cell i with condition $c(i)$, its position along the developmental path $\mathcal{T}_{c(i)}$ is defined by a
 73 vector of $L_{c(i)}$ pseudotimes \mathbf{T}_i and a unit-norm vector of $L_{c(i)}$ weights \mathbf{W}_i ($\|\mathbf{W}_i\|_1 = 1$) (i.e., there is
 74 one pseudotime and one weight per lineage), with

$$\mathbf{T}_i \sim G_{c(i)} \text{ and } \mathbf{W}_i \sim H_{c(i)}. \quad (1)$$

75 The cumulative distribution functions (CDF) G_c and H_c are condition-specific and we make limited
 76 assumptions on their properties (see the [method section](#) for details). The pseudotime values represent
 77 how far a cell has progressed along each lineage, while the weights represent how likely it is that a cell
 78 belongs to each lineage. The gene expression model will be described below. Using this notation, we can
 79 properly define a trajectory inference (TI) method as a function that takes as input \mathbf{Y} – and potentially
 80 other arguments – and returns estimates of L_c , \mathbf{T} , \mathbf{W} , and eventually \mathcal{T}_c .

81 **Step 1 - Differential Topology: Should we fit a common trajectory?** The first question to ask
 82 in our workflow is: Should we fit a common trajectory to all cells regardless of their condition? Or are the
 83 developmental trajectories too dissimilar between conditions? To demonstrate what this means, consider
 84 two extremes. For a dataset that consists of a mix of bone marrow stem cells and epithelial stem cells,
 85 using tissue as our condition, it is obvious that the developmental trajectories of the two conditions are
 86 not identical and should be estimated separately. On the other hand, if we consider a dataset where only
 87 a few genes are differentially expressed between conditions, the impact on the developmental process will
 88 be minimal and it is sensible to estimate a single common trajectory.

89 Indeed, we favor fitting a common trajectory for several reasons. Firstly, fitting a common trajectory
 90 is a more stable procedure since more cells are used to infer the trajectory. Secondly, our workflow still

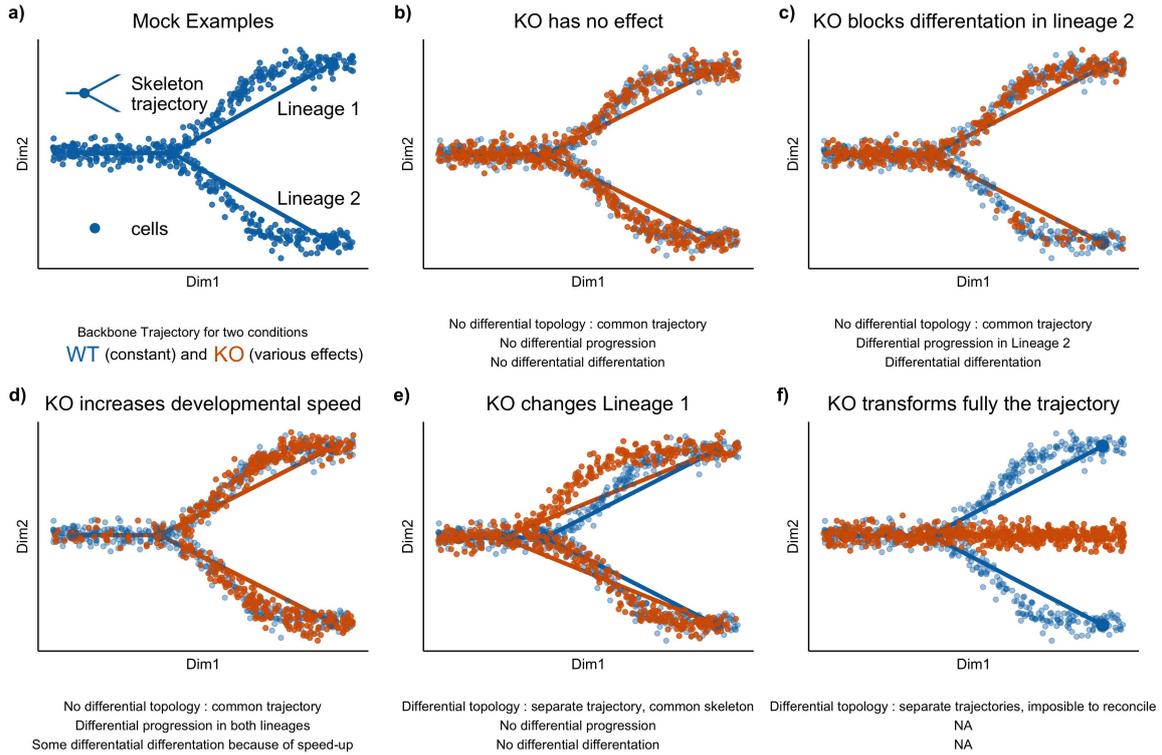

Figure 1: *Illustrating the first two steps of the condiments workflow with several scenarios (a.)* The examples are all built on a similar wild-type backbone, i.e., two lineages that slowly diverge in the absence of knocking out. Cells either originate from a wild-type (WT, blue) or a knock-out (KO, orange) condition. In (b.), the knock-out has no effect, all three tests fail to reject their null hypothesis. In (c.), the knock-out partly blocks differentiation along Lineage 2, meaning that fewer cells develop along that lineage. In this case, while the `topologyTest` fails to reject the null, we have both differential progression along Lineage 2 and differential differentiation. In (d.), the knock-out speeds development, so there are more orange cells toward the end of both lineages. This leads to both differential progression and differentiation. In (e.), the knock-out modifies the intermediate stage for Lineage 1 and changes where the lineages bifurcates; based on the `topologyTest`, we fit one trajectory per condition. However, the skeleton structure is unchanged, so there is a mapping between the two trajectories and we can still test for differential progression and differentiation. In both cases, we fail to reject the null. Finally, in (f.), the knock-out fully disrupts the developmental process: all cells in the knock-out condition progress along a new lineage. Here, we fit separate trajectories and these cannot be reconciled easily, so we cannot proceed to Steps 2 and 3.

91 provides a way to test for differences between conditions along and between lineages even if a common
 92 trajectory is inferred. In particular, fitting a common trajectory between conditions does not require that
 93 cells of distinct conditions differentiate similarly along that trajectory. Finally, fitting different trajec-
 94 tories greatly complicates downstream analyses since we may need to map between distinct developmen-
 95 tal structures before comparing them (i.e., each lineage in the first trajectory must match exactly one lin-
 96 eage in the second trajectory). Therefore, our workflow recommends fitting a common trajectory if the
 97 differences between conditions are *small enough*.

98 To quantify what *small enough* is, we rely on two approaches. The first is a qualitative diagnostic tool
 99 called *imbalance score*. It requires as input a reduced-dimensional representation \mathbf{X} of the data \mathbf{Y} and the
 100 condition labels. Each cell is assigned a score that measures the imbalance between the local and global
 101 distributions of condition labels. Similarly to Dann et al. [16], Burkhardt et al. [18], the neighborhood
 102 of a cell is defined using a k -nearest neighbor graph on \mathbf{X} , which allows the method to scale very well
 103 to large values of n . Cell-level scores are then locally scaled using smoothers in the reduced-dimensional
 104 space (see the [Methods section](#)).

105 However, visual representation of the scores may not always be enough to decide whether or not to
 106 fit a common trajectory in less obvious cases. Therefore, we introduce a more principled approach, the

107 `topologyTest`. This test assesses whether we can reject the following null hypothesis:

$$H_0 : \forall (c_1, c_2) \in \{1, \dots, C\}^2, \mathcal{T}_{c_1} = \mathcal{T}_{c_2}. \quad (2)$$

108 Under the null, the trajectory is common among all conditions and can therefore be estimated using all
109 cells. Therefore, an estimation of the pseudotime vectors done by inferring a trajectory for each condition
110 should be equivalent to the same procedure after permuting the condition labels. This is what is done
111 for the `topologyTest`. A set of pseudotime vectors is estimated with the true condition labels. Another
112 set is generated using permuted labels. Under the null, these two distributions should be equal. We can
113 therefore test hypothesis (2) by testing for the equality in distributions of pseudotime using a variety of
114 statistical tests (see the [Methods section](#) for details). Since we want to favor fitting a common trajectory
115 and we only want to discover cases that are not only statistically significant but also biologically relevant,
116 the tests typically include a minimum magnitude requirement for considering the difference between
117 distributions to be significant (similar to a minimum log-fold-change for assessing DE). More details and
118 practical implementation considerations are discussed in the [Methods section](#).

119 In practice, the `topologyTest` requires maintaining a mapping between each of the trajectories,
120 both between conditions and between permutations (see the [Methods section](#) where we define a mapping
121 precisely). Trajectory inference remains a semi-supervised task, that generally cannot be fully automated.
122 In particular, the number of estimated lineages might change between different permutations for a given
123 condition, precluding a mapping. As such, the `topologyTest` is only compatible with certain TI methods
124 that allow for the specification of an underlying skeleton structure [2, 4], where the adjacency matrix can
125 be pre-specified, as well (optionally) start and/or end states.

126 In the examples from Fig 1, the skeleton of the trajectory is represented by a series of nodes and
127 edges. In examples 1b-d, the knock-out has no impact on this skeleton compared to the wild-type. In
128 example 1e, the knock-out (KO) modifies the skeleton, in that the locations of the nodes change. However,
129 the adjacency matrix does not change and the two skeletons represent isomorphic graphs: the skeleton
130 structure is preserved.

131 For some TI methods [2, 4], it is possible to specify and preserve this skeleton structure. This means
132 that the mapping of lineages can be done automatically. The `topologyTest` utilises this, and is thus
133 restricted to such TI methods. This common skeleton structure can also be used if the null of the
134 `topologyTest` is rejected. The availability of a mapping between lineages means that the next steps of
135 the workflow can be conducted as if we had failed to reject the null hypothesis, as done in Fig 1e. The
136 third case study will also present an example of this.

137 Even if the null is rejected by the `topologyTest` and separate trajectories must be fitted for each
138 condition, a common skeleton structure can still be used to map between trajectories. This mapping
139 means that the next steps of the workflow can be conducted as if we had failed to reject the null hypothesis,
140 as done in Fig 1e. The third case study will also present an example of this. In cases where no common
141 skeleton structure exists, such as Fig 1f, no automatic mapping exists. Differential abundance can be
142 assessed but requires a manual mapping. Differential expression can still be conducted as well.

143 **Step 2 - Differential abundance: What are the global differences between conditions?** The
144 second step of the workflow focuses on differences between conditions at the trajectory level. It requires
145 either a common trajectory, or multiple trajectories and a mapping. We can then ask whether cells from
146 different conditions behave similarly as they progress along the trajectory. To facilitate the interpretation
147 of the results, we break this into two separate questions. Note that, at this step and the next, we are no
148 longer limited to specific TI methods. Moreover, the mapping can be partial. In that case, Step 2 will
149 be restricted to the parts (or subgraphs) of the trajectories that are mappable. See the [Methods section](#)
150 for proper definitions of mapping and partial mapping.

151 **Step 2a: Differential Progression.** Although the topology might be common, cells might progress
152 at different rates along the lineages for different conditions. For example, a treatment might limit the
153 differentiation potential of the cells compared to the control, or instead speed it up. In the first case,
154 one would expect to have more cells at the early stages and fewer at the terminal state, when comparing
155 treatment and control. Using our statistical framework, testing for differential progression amounts to
156 testing:

$$H_0 : \forall (c_1, c_2) \in \{1, \dots, C\}^2, G_{c_1} = G_{c_2}. \quad (3)$$

157 This test can also be conducted at the individual-lineage level. If we denote by G_{lc} the l^{th} component
158 of the distribution function G_c , we can test for differential progression along lineage l by considering the

159 null hypothesis:

$$H_0 : \forall(c_1, c_2) \in \{1, \dots, C\}^2, G_{lc_1} = G_{lc_2}. \quad (4)$$

160 We can assess either or both null hypotheses in the `progressionTest`, which relies on non-parametric
161 tests to compare two or more distributions, e.g., the Kolmogorov-Smirnov test [19] or the classifier
162 test [20]. More details and practical implementation considerations are discussed in the [Methods Section](#).

163 **Step 2b: Differential Differentiation.** Although the topology might be common, cells might also
164 differentiate in varying proportions between the lineages for different conditions. For example, an in-
165 tervention might lead to preferential differentiation along one lineage over another, compared to the
166 control condition; or might alter survival rates of differentiated cells between two end states. In both
167 cases, the weight distribution will be different between the control and treatment. Assessing differential
168 differentiation at the global level amounts to testing, in our statistical framework, the null hypothesis

$$H_0 : \forall(c_1, c_2) \in \{1, \dots, C\}^2, H_{c_1} = H_{c_2}. \quad (5)$$

169 This test can also be conducted for a single pair of lineages (l, l') :

$$H_0 : \forall(c_1, c_2) \in \{1, \dots, C\}^2, [H_{lc_1}, H_{l'c_1}] = [H_{lc_2}, H_{l'c_2}]. \quad (6)$$

170 The above null hypotheses can again be tested by relying on non-parametric test statistics. We also
171 discuss specific details and practical implementation in the [Methods section](#).

172 The `progressionTest` and `differentiationTest` are quite linked since the functions G_c and H_c are
173 correlated and will therefore often return similar results. However, they do answer somewhat different
174 questions. In particular, looking at single-lineage (`progressionTest`) and lineage-pair (`differentiationTest`)
175 test statistics will allow for a better understanding of the global differences between conditions. Differ-
176 ential differentiation does not necessarily imply differential progression and vice versa.

177 **Step 3 - Differential Expression: Which genes have different expression patterns between**
178 **conditions?** Steps 1 and 2 focus on differences at a global level (i.e., aggregated over all genes) and
179 will detect large changes between conditions. However, such major changes are ultimately driven by
180 underlying differences in gene expression patterns. Furthermore, even in the absence of global differences,
181 conditions might still have some more subtle impact at the gene level. In the third step, we therefore
182 compare gene expression patterns between conditions for each of the lineages. Step 3 is even more general
183 than Step 2, in that it can be used without mapping between trajectories, i.e., some or all lineages could
184 be condition-specific.

185 Following the `tradeSeq` manuscript by Van den Berge et al. [8], we consider a general and flexible
186 model for gene expression, where the gene expression measure Y_{ji} for gene j in cell i is modeled with
187 the negative binomial generalized additive model (NB-GAM) described in Equation (13). We extend the
188 `tradeSeq` model by additionally estimating condition-specific average gene expression profiles for each
189 gene. We therefore rely on lineage-specific, gene-specific, and condition-specific smoothers, s_{jlc} . With
190 this notation, we can introduce the `conditionTest`, which, for a given gene j , tests the null hypothesis
191 that these smoothers are identical across conditions:

$$H_0 : s_{jlc_1} = s_{jlc_2}, \forall(c_1, c_2), \forall l. \quad (7)$$

192 As in `tradeSeq`, we rely on the Wald test to test H_0 in terms of the smoothers' regression coefficients.
193 We can also use the fitted smoothers to visualize gene expression along lineages between conditions or
194 cluster genes according to their expression patterns.

195 Simulations

196 We generate multiple trajectories using the simulation framework provided by Cannoodt et al. [22].
197 Within this framework, it is possible to knock out a specific gene. Here, we knock out a master regulator
198 that drives differentiation into the second lineage. The strength of this knock-out can be controlled via
199 a multiplier parameter m . If $m = 0$, the knock-out is total. If $0 < m < 1$, we have partial knock-out. If
200 $m > 1$, the master regulator is over-expressed and cells differentiate much faster along the second lineage.

201 Three types of datasets are generated: Simple branching trajectories (two lineages, e.g., Fig. 2a) of
202 3, 500 cells, with equal parts wild-type and knock-out; trajectories with two consecutive branchings (and
203 thus three lineages, e.g., Fig. 2b) of 3, 500 cells, with equal parts wild-type and knock-out; and branching

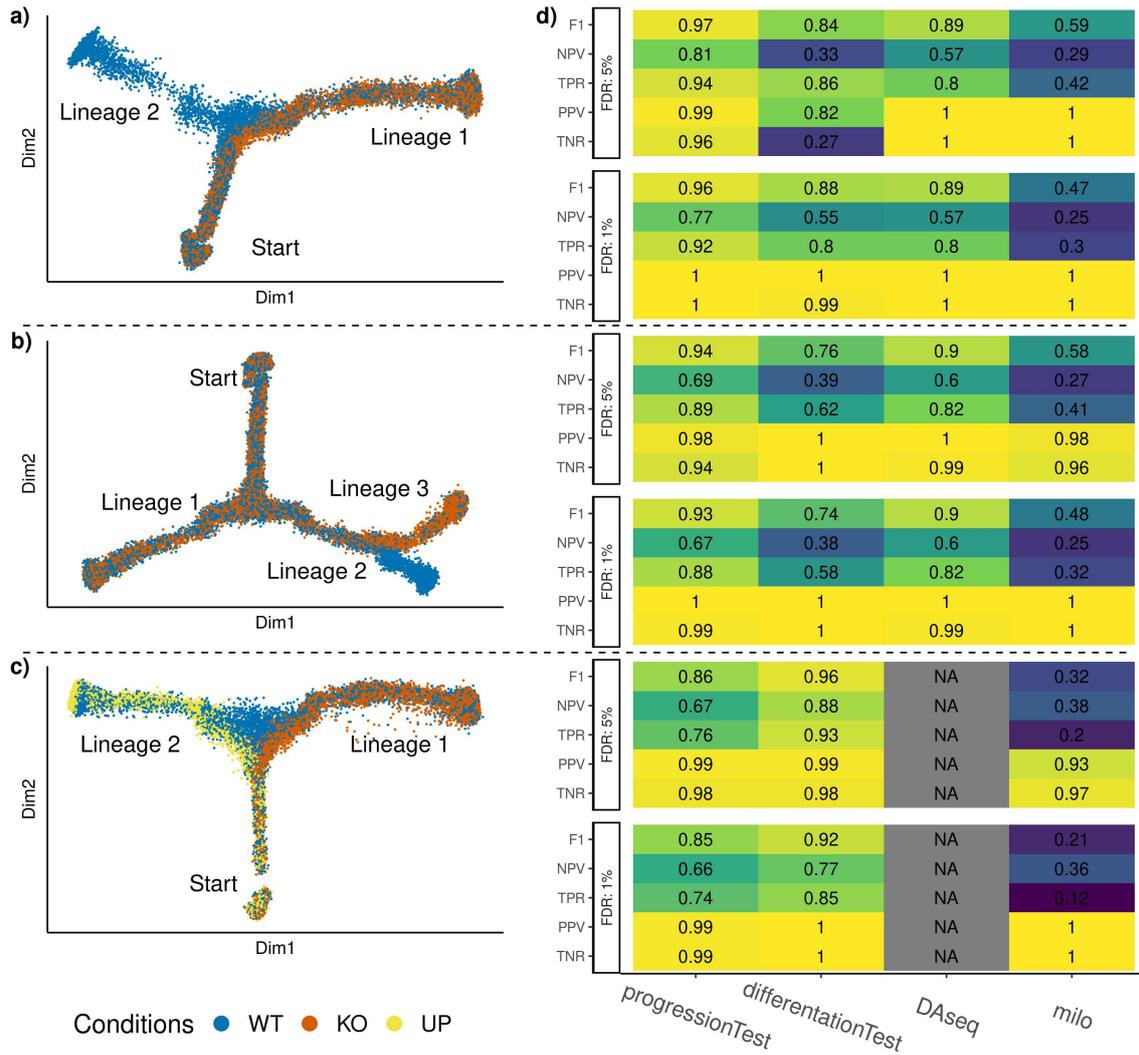

Figure 2: *Simulation results*. Three types of datasets are generated, with respectively two, three, and two lineages, and two, two, and three conditions. Reduced-dimensional representations of these datasets, for a multiplier value of $m = .5$, are presented in (a.), (b.), and (c.), respectively. After generating multiple versions of the datasets for a range of values of m , we compare the performance of the `progressionTest` and `differentiationTest` with that of `DAseq`[17] and `milo`[16], when controlling the false discovery rate at nominal levels 1% and 5% using the Benjamini-Hochberg [21] procedure. In (d.), each cell represents the performance measure associated with one test on one dataset for one nominal FDR level. Cells are also colored according to the performance. Overall, with two conditions, the `progressionTest` ranks first, followed by `DAseq` and the `differentiationTest`. With three conditions, the `differentiationTest` ranks first. `DAseq` is limited to two conditions. Exact simulation parameters and metrics are specified in the [Methods section](#).

204 trajectories (two lineages) of 5,000 cells with three conditions, wild-type, knock-out with multiplier m ,
 205 and induction with multiplier $1/m$ (Fig. 2c).

206 The simulation framework cannot, however, generate distinct trajectories for the different conditions,
 207 so we start the `condiments` workflow at Step 2, downstream of `slingshot`. We compare the `progressionTest`
 208 and `differentiationTest` from `condiments` to methods that also do not rely on clustering, but instead
 209 take into account the continuum of differentiation. `milo` [16] and `DAseq`[17] both define local neighbor-
 210 hoods using k -nearest neighbors graphs and look at differences of proportions in these neighborhood to
 211 test for differential abundance. These methods returns multiple tests per dataset (i.e., one per neigh-
 212 borhood), so we adjust for multiple hypothesis testing using the Benjamini-Hochberg procedure [21]. By
 213 applying `milo`, `DAseq`, and `condiments` on the simulated datasets, we can compare the results of the tests

Table 1: *Summary of all case study datasets.* We report the name, number of cells n , number of conditions C , number of lineages L of each dataset, as well as the p-value resulting from testing for differential topology, progression and differentiation and the number of differentially expressed genes between conditions according to the `conditionTest`

Dataset	n	C	L	topology	progression	differentiation	DE
TGFB [9]	9,268	2	1	0.38	$\leq 2.2 \times 10^{-16}$	NA	1,993
TCDD [10]	9,951	2	1	0.07	$\leq 2.2 \times 10^{-16}$	NA	2,144
KRAS [23]	10,177	3	3	$\leq 2.2 \times 10^{-16}$	$\leq 2.2 \times 10^{-16}$	$\leq 2.2 \times 10^{-16}$	363

versus the values of m : We count a true positive when a test rejects the null and $m \neq 1$, and a true negative if the test fails to reject the null and $m = 1$.

We compare the methods' ability to detect correct differences between conditions using five metrics: The true negative rate (TNR), positive predictive value (PPV), true positive rate (TPR), negative predictive value (NPV), and F1-score, when controlling the FDR at two nominal levels of 1% and 5%. More details on the simulation scenarios and metrics can be found in the [Methods section](#). Results are displayed in Fig. 2d.

On all simulations, all methods display excellent results for the TNR and PPV (except for the `differentiationTest` with level 1% on the branching dataset). However, the performances for the TPR (power), NPV, and F1-rate vary quite widely. On the two types of datasets with two conditions, the ranking is uniform over all metrics and levels: `progressionTest`, `Daseq`, `differentiationTest`, and `milo`. On the third simulation setting with three conditions, we cannot benchmark `Daseq` since its testing framework is restricted to two conditions. Here, also, the ranking is uniform but the `differentiationTest` outperforms the `progressionTest`. Looking more closely at the results, we can see (Fig S2) that this mostly stems from increased power for the `differentiationTest` when m is close to 1.

Overall, the tests from the `condiments` workflow offer a flexible approach that can handle various scenarios and still outperform competitors.

Case studies

We consider three real datasets as case studies for the application of the `condiments` workflow. Table 1 gives an overview of these datasets and summary results. These case studies aim to demonstrate the versatility and usefulness of the `condiments` workflow, as well as showcase how to interpret and use the tests in practice.

TGFB dataset

McFaline-Figueroa et al. [9] studied the epithelial-to-mesenchymal transition (EMT), where cells migrate from the epithelium (inner part of the tissue culture dish) to the mesenchyme (outer part of the tissue culture dish) during development. The developmental process therefore is both temporal and spatial. As cells differentiate, gene expression changes. Moreover, the authors studied this system under two settings: a mock (control) condition and a condition under activation of transforming growth factor β (TGFB).

After pre-processing, normalization, and integration (see details in the [supplementary methods](#)), we have a dataset of 9,268 cells, of which 5,207 are mock and 4,241 are TGFB-activated. The dataset is represented in reduced dimension using UMAP[24] (Fig. 3a). Adding the spatial label of the cells (Fig. 3b) shows that the reduced-dimensional representation of the gene expression data captures the differentiation process.

We can then run the `condiments` workflow. The imbalance score of each cell is computed and displayed in Fig. 3c. Although some regions do display strong imbalance, there is no specific pattern along the developmental path. This is confirmed when we run the `topologyTest`. The nominal p -value of the associated test is 0.38. We clearly fail to reject the null hypothesis and we consequently fit a common trajectory to both conditions using `slingshot` with the spatial labels as clusters. This single-lineage trajectory is shown in Fig. 3d.

Next, we can ask whether the TGFB treatment impacts the differentiation speed. The developmental stage of each cell is estimated using its pseudotime. Plotting the per-condition kernel density estimates of pseudotimes in Fig. 3e reveals a strong treatment effect. The pseudotime distribution for the mock cells is trimodal, likely reflecting initial, intermediary, and terminal states. However, the first mode is not present in the TGFB condition, and the second is skewed towards higher pseudotime values. This is

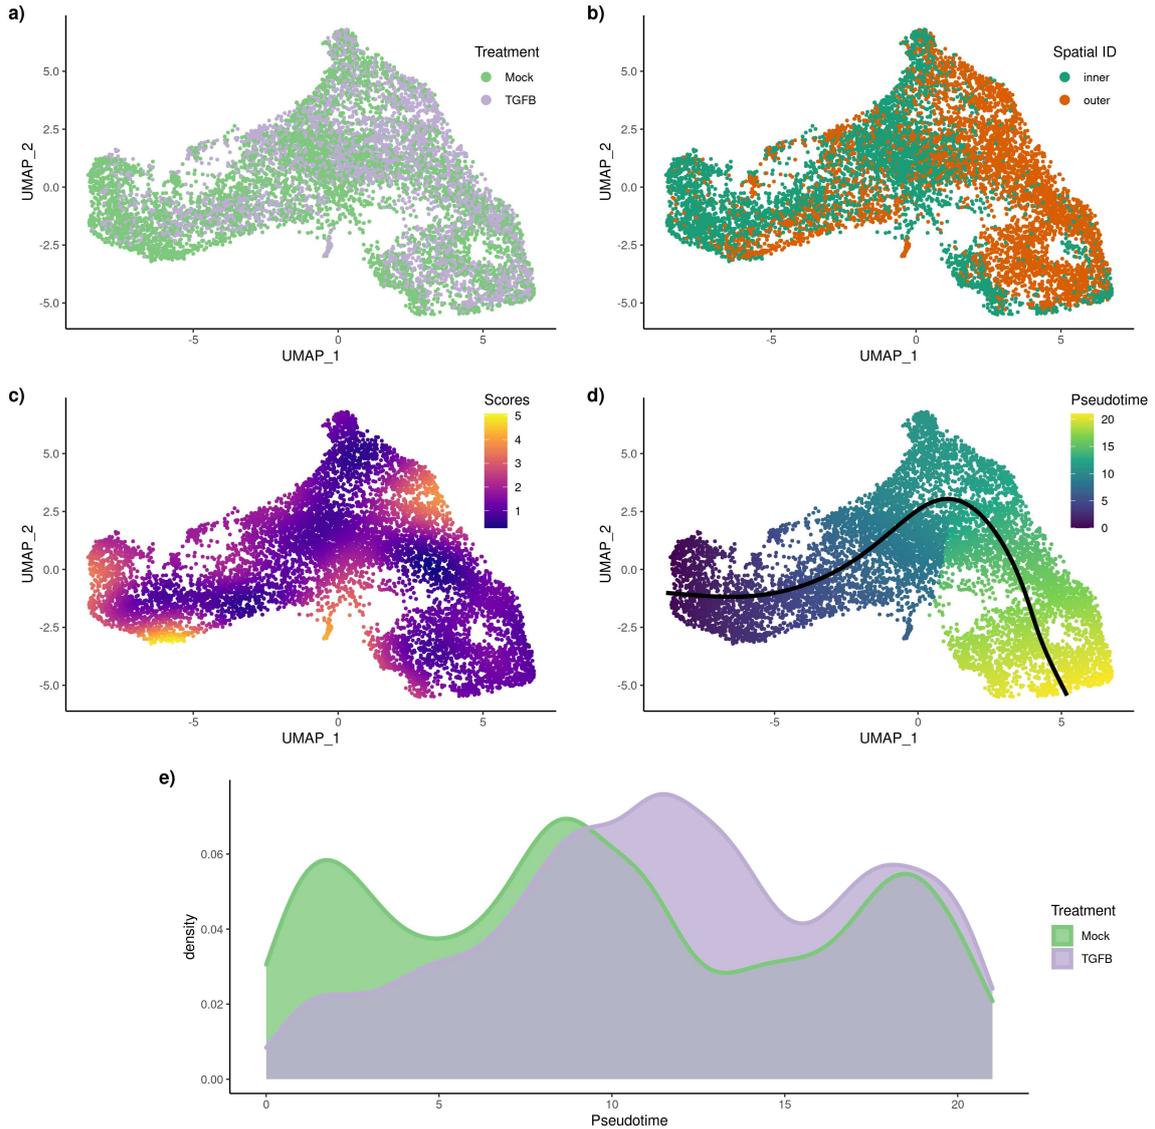

Figure 3: *TGFβ* dataset: *Differential topology and differential progression*. After normalization and projection on a reduced-dimensional space (using UMAP), the cells can be colored either by treatment label (a.) or spatial origin (b.). Using the treatment label and the reduced-dimensional coordinates, an imbalance score is computed and displayed (c.). The `topologyTest` fails to reject the null hypothesis of no differential topology and a common trajectory is therefore fitted (d.). However, there is differential progression between conditions: the pseudotime distributions along the trajectory are not identical (e.) between conditions and we reject the null using the `progressionTest`.

258 very consistent with the fact that the treatment is a growth factor that would increase differentiation, as
 259 shown in the original publication. Testing for equality of the two distributions with the `progressionTest`
 260 confirms the visual interpretation. The nominal p -value associated with the test is smaller than 2.2×10^{-16}
 261 and we reject the null that the distributions are identical. Since the trajectory is limited to one lineage,
 262 there is no possible differential differentiation between pairs of lineages.

263 Then, we proceed to identifying genes whose expression patterns differ between the mock and TGFβ
 264 conditions. After gene filtering, we fit smoothers to 10,549 genes, relying on the model described in
 265 Equation (13). We test whether the smoothers are significantly different between conditions using the
 266 `conditionTest`. Testing against a log-fold-change threshold of 2, we find 1,993 genes that are dynamically
 267 differentially expressed between the two conditions when controlling the false discovery rate (FDR) at
 268 a nominal level of 5%. Fig. 4a and b show the two genes with the highest Wald test statistic. The
 269 first gene, *LAMC2*, was also found to be differentially expressed in the original publication and has been

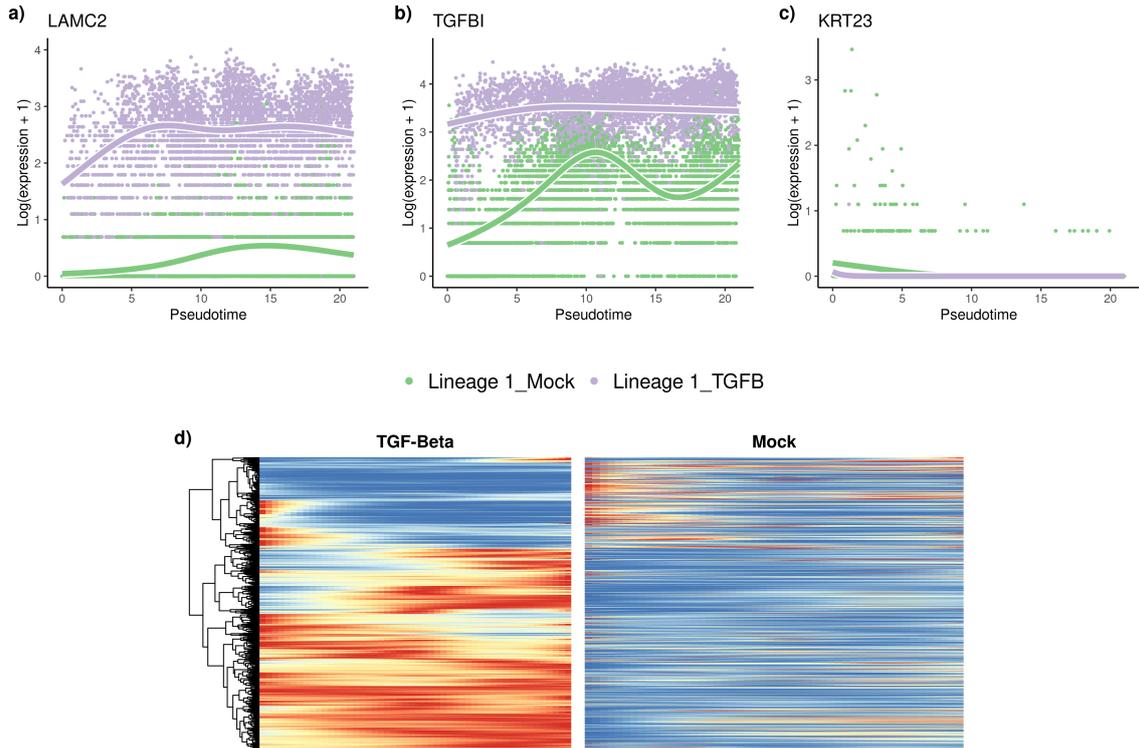

Figure 4: **TGFβ** dataset: *Differential expression*. The tradeSeq gene expression model is fitted using the trajectory inferred by slingshot. Differential expression between conditions is assessed using the `conditionTest` and genes are ranked according to the test statistics. The genes with the highest (a.), second highest (b.), and smallest (c.) test statistics are displayed. After adjusting the p -values to control the FDR at a nominal level of 5%, we display genes for both conditions using a pseudocolor image (d.) after scaling each gene to a $[0, 1]$ range.

270 shown to regulate EMT [25]. The second gene, *TGFB1* or TGFβ-induced gene, is not surprising, and was
 271 also labelled as differentially expressed in the original publication. In contrast, the gene that is deemed
 272 the least differentially expressed exhibits no differences between the smoothers (Fig. 4c.). Looking at all
 273 1, 993 DE genes, we can cluster and display their expression patterns along the lineage for both conditions
 274 (Fig. 4) and identify several groups of genes that have different patterns between the two conditions.

275 Finally, we perform a gene set enrichment analysis on all the genes that are differentially expressed
 276 between the conditions. The full results are available in Supplementary Table S1. Top annotations
 277 include gene sets involved in cell motility, adhesion, and morphogenesis, which are consistent with the
 278 expected biology.

279 TCDD dataset

280 Nault et al. [10] collected a dataset of 16,015 single nuclei to assess the hepatic effects of 2,3,7,8-
 281 tetrachlorodibenzo-p-dioxin or TCDD. In particular, they focused on the effect of TCDD on the 9,951
 282 hepatocytes cells along the central-portal axis. This dataset is not a developmental dataset per se but still
 283 exhibits continuous changes along a spatial axis, demonstrating the versatility of the trajectory inference
 284 framework in general, and of the condiments workflow in particular.

285 Fig. S3a shows a reduced-dimensional representation of the dataset, with cells labelled according to
 286 treatment/control condition, while Fig. S3b shows the same plot colored by cell type, as derived by the
 287 authors of the original publication. The cells are aligned in a continuum, from central to mid-central and
 288 then mid-portal and portal. The imbalance score shows some spatial pattern (Fig. S3c). However, the
 289 nominal p -value associated with the `topologyTest` is .07. We therefore fail to reject the null and we infer
 290 a common trajectory using `slingshot` on the spatial clusters. This results in a single-lineage trajectory
 291 that respects the ordering of the spatial clusters (Fig. S3d). Note that, since the trajectory reflects a
 292 spatial continuum rather than a temporal one, the start of the trajectory is arbitrary. However, inverting

293 the start and end clusters amounts to an affine transformation of the pseudotimes for all the cells. Step
294 2 and 3 are fully invariant to this transformation, so we can pick the Central cluster as the start of the
295 trajectory.

296 The densities of the treatment and control pseudotime distributions differ greatly visually (Fig. S3e),
297 with the TCDD density heavily skewed toward the start of the trajectory. Indeed, the `progressionTest`
298 has a nominal p -value $\leq 2.2 \times 10^{-16}$. This coincides with the finding of the original publication which
299 highlighted the periportal hepatotoxicity of TCDD.

300 The ability of the `progressionTest` to correctly find large-scale changes in the spatial distribution
301 of cells between conditions underscores why we favor fitting a common trajectory. Indeed, the p -value of
302 the `topologyTest` in Step 1 is rather small and would have been below .05 if we had not conducted a
303 test against a threshold. However, testing against a threshold and thus fitting a common trajectory does
304 not stop the workflow from finding large-scale differences between conditions in Step 2 and results in a
305 more stable estimate of the trajectory.

306 After gene filtering, we test 8,027 genes for spatial differential expression between conditions and we
307 find 2,114 DE genes when controlling the FDR at a nominal level of 5%. The genes with the largest,
308 second largest, and smallest test statistics are displayed in Fig.S4a-c. Similarly to Nault et al. [10], we
309 obtain a list of zonal genes from Halpern et al. [26]. The proportion of zonal genes among the DE genes
310 is twice their proportion among non-DE genes.

311 **KRAS dataset**

312 Xue et al. [23] studied the impact of KRAS(G12C) inhibitors at the single-cell level on three models
313 of KRAS(G12C) lung cancers. Specifically, they examined how various cell populations react to these
314 inhibitors and how some cells can return in proliferation mode shortly after the end of the treatment.
315 Here, we want to investigate how the three cancer models (H358, H2122, and SW1573) differ in their
316 response to the KRAS(G12C) inhibitors.

317 We use the reduced-dimensional representation from the original paper to display the 10,177 cells
318 from the various types (Fig 5a). Using the cancer type labels and the reduced-dimensional coordinates,
319 an imbalance score can be computed (Fig 5b); some regions clearly show an imbalance. This is further
320 confirmed by the `topologyTest`, with p -value smaller than 2.2×10^{-16} . We therefore do not fit a common
321 trajectory to all cancer types (Fig 5c).

322 Note that this does not necessarily imply that the trajectory of reaction to the KRAS(G12C) inhibitors
323 is different between cancer types. Indeed, this may also reflect strong batch effects between conditions,
324 which the normalization scheme was unable to fully remove when integrating the three cancer types in
325 one common reduced-dimensional representation. Thus, it is not really possible to draw a biological
326 conclusion at this first step. However, this does mean that a separate trajectory should be fitted to each
327 condition.

328 Here, the trajectories, although different, are similar enough that we can still use an underlying
329 common skeleton (Fig 5d). Indeed, we keep the tree structure derived by computing the minimum
330 spanning tree (MST) on the clusters using all cells. This way, it is possible to derive a one-to-one mapping
331 between the lineages of the three trajectories and we respect the assumptions detailed in Section 1.2 that
332 are necessary for the `progressionTest` and `differentiationTest`.

333 Using this common mapping, we can then proceed to the `progressionTest`. At the global trajectory
334 level, the nominal p -value is smaller than 2.2×10^{-16} , showing clear differential progression. At the lineage
335 level, all three lineages show strong differential progression, with p -values of 2.2×10^{-16} , 1.2×10^{-12} ,
336 and 1.2×10^{-14} , respectively. The density plots for the pseudotime distributions at the single-lineage
337 level (Fig 5e) indicate that the differential progression is driven by a group of cells from cancer type
338 H2122A. This matches the top left part of the reduced-dimensional plot, the region where cells exit the
339 initial inhibition stage to enter the reactivation stage. The second lineage also shows a difference between
340 H2122A and the two other models. The pseudotime distribution is heavily skewed toward earlier points
341 in that model compared to the other two. Lineage 2 represents differential progression to a drug-induced
342 state. In Lineage 3, it is the SW1573A model that displays more differential progression.

343 The `differentiationTest` also has a p -value smaller than 2.2×10^{-16} . Although all pairwise compar-
344 isons are significant, the test statistics are much higher for the Lineage 2 vs. 1 and Lineage 2 vs. 3
345 comparisons. This again suggests that one model differentiates less into the drug-induced path, compared
346 to the other two. Since the weights have to sum to 1, the 3-dimensional distribution can be fully sum-
347 marized by any two components. Fig S5 shows clear differences in distributions but visually interpreting
348 different 2D distributions is still challenging. A simpler way to compare the distributions is to look at the
349 average weight in each condition for each lineage (Fig 5f). This ignores the correlation between lineages

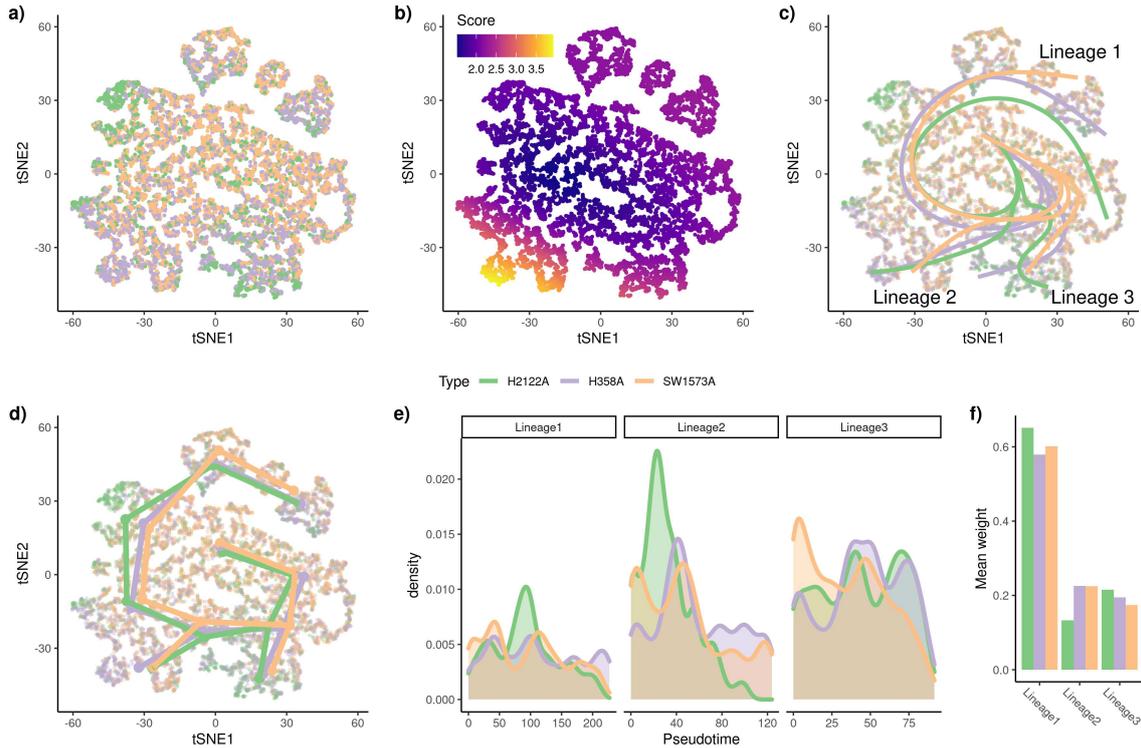

Figure 5: *KRAS* dataset: *Differential topology, differential progression, and differential differentiation.* Using the reduced-dimensional representation of the original publication (t-SNE), the cells can be colored by cancer type (a.). Using the cancer type label and the reduced-dimensional coordinates, an imbalance score is computed and displayed (b.). The `topologyTest` rejects the null hypothesis of a common trajectory, we thus fit one trajectory per condition (c.). However, the skeleton graphs have the same structure (d.), so we can progress to the next steps in the condiments workflow. There is differential progression (d.) and we indeed reject the null of identical pseudotime distributions along the trajectory using the `progressionTest`. Similarly, there is differential differentiation (e.) and we reject the null of identical weight distributions along the trajectory using the `differentiationTest`. Here, we summarize the distributions by looking at the average weight for each lineage in each condition, which already shows some clear differences.

350 but still allows for some interpretation. We can see in particular that Lineages 1 and 3 have greater
 351 weights for H2122A than for the other two conditions, which is consistent with the different pairwise
 352 statistics.

353 With the mapped trajectories, we can also perform gene-level analysis using the `conditionTest`.
 354 When comparing genes across all lineages and conditions, we find 363 differentially expressed genes when
 355 controlling the FDR at nominal level 5%. We show the genes with the highest, second highest, and
 356 smallest test statistics in Fig. S6a-c. Displaying these global patterns across all three lineages and all
 357 three conditions makes it hard to interpret. We therefore focus on the first (and longest) lineage. In that
 358 lineage, we find 366 DE genes and we show their expression patterns along Lineage 1 in all three cancer
 359 models in Fig. S6d.

360 Discussion

361 In this manuscript, we have introduced `condiments`, a full workflow to analyze dynamic systems under
 362 multiple conditions. By separating the analysis into several steps, `condiments` offers a flexible framework
 363 with increased interpretability. Indeed, we follow a natural progression through a top-down approach, by
 364 first studying overall differences in trajectories with the `topologyTest`, then differences in abundances
 365 at the trajectory level with the `progressionTest` and `differentiationTest`, and finally gene-level
 366 differences in expression with the `conditionTest`.

367 As demonstrated in the simulation studies, taking into account the dynamic nature of systems via
368 the trajectory representation enables `condiments` to better detect true changes between conditions. The
369 flexibility offered by our implementation, which provides multiple tests for non-parametric comparisons
370 of distributions, also allows us to investigate a wide array of scenarios. This is evident in the three case
371 studies presented in the manuscript. Indeed, in the first case study we have a developmental system
372 under treatment and control conditions, while in the second case study the continuum does not represent
373 a developmental process but spatial separation. In the third case study, the conditions do not reflect
374 different treatments but instead different cancer models. This shows that `condiments` can be used to
375 analyze a wide range of datasets.

376 Often, the different conditions also represent different batches. Indeed, some interventions cannot be
377 delivered on a cell-by-cell basis and this creates unavoidable confounding between batches and conditions.
378 Normalization and integration of the datasets must therefore be done without eliminating the underlying
379 biological signal. This balance can be hard to strike, as discussed in Zhao et al. [17]. Proper experimental
380 design – such as having several batches per condition – or limiting batch effects as much as possible –
381 for example, sequencing a mix of conditions together – can help lessen this impact. Still, some amount
382 of confounding is sometimes inherent to the nature of the problem under study.

383 The tests used in the workflow (e.g., Kolmogorov-Smirnov test) assume that the pseudotime and
384 weight vector are known and independent observations for each cell. However, this is not the case:
385 they are estimated using TI methods which use all samples to infer the trajectory, and each estimate
386 inherently has some uncertainty. Here, we ignore this dependence, as is the case in other differential
387 abundance methods, which assume that the reduced-dimensional coordinates are observed independent
388 random variables even though they are being estimated using the full dataset. We stress that, rather
389 than attaching strong probabilistic interpretations to p -values (which, as in most RNA-seq applications,
390 would involve a variety of hard-to-verify assumptions and would not necessarily add much value to the
391 analysis), we view the p -values produced by the `condiments` workflow as useful numerical summaries
392 for guiding the decision to fit a common trajectory or condition-specific trajectories and for exploring
393 trajectories across conditions and identifying genes for further inspection.

394 Splitting the data into two groups, where the first is used to estimate the trajectory and the second
395 is used for pseudotime and weight estimation could, in theory, alleviate the dependence issue, at the cost
396 of smaller sample sizes. However, this would ignore the fact that, in practice, users perform exploratory
397 steps using the full data before performing the final integration, dimensionality reduction, and trajectory
398 inference. Moreover, results on simulations show that all methods considered keep excellent control of the
399 false discovery rate despite the violation of the independence assumptions. This issue of “double-dipping”
400 therefore seems to have a limited impact.

401 The two issues raised in the previous paragraphs highlight the need for independent benchmarking.
402 Simulation frameworks such as `dyngen` [22] are crucial. They also need to be complemented by real-world
403 case studies, which will become easier as more and more datasets that study dynamic systems under
404 multiple conditions are being published. `condiments` has thus been developed to be a general and flexible
405 workflow that will be of use to researchers asking complex and ever-changing questions.

410 Authors' contributions

411 Data and code availability

412 The results from this paper can be fully reproduced by following along the vignettes at <https://hectorrdb.github.io/condimentsPaper>. These also contain the code needed to recreate the datasets
413 used for the simulations, as well as processed versions of all three datasets used in the case studies, aug-
414 mented by metadata and functions to recreate the processed versions, using raw counts obtained from
415 GEO (**TGFB** dataset: GSE114687, **TCDD** dataset: GSE148339, **KRAS** dataset: GSE137912).

416 The `condiments` workflow is available as an R package from Github (<https://github.com/HectorRDB/condiments>) and will be made available through the Bioconductor Project.

417 All the methods to test for equality of two (or k) distributions have been put together for use by
418 others in an R package called `Ecume`, available through CRAN and that can be explored at <https://>

421 [//hectorrdb.github.io/Ecume](https://hectorrdb.github.io/Ecume).

422 Competing interests

423 The authors declare that they have no competing interests.

424 Methods

425 1.1 Tests for equality of distributions

426 1.1.1 General setting

427 Consider a set of n i.i.d. observations, \mathbf{X} , with $\mathbf{X}_i \sim \mathbf{P}_1$, and a second set of m i.i.d. observations, \mathbf{Y} ,
428 with $\mathbf{Y}_j \sim \mathbf{P}_2$, independent from \mathbf{X} . For example, in our setting, \mathbf{X} and \mathbf{Y} may represent estimated
429 pseudotimes for cells from two different conditions. We limit ourselves to the case where \mathbf{X} and \mathbf{Y} are
430 random vectors of the same dimension d .

431 The general goal is to test the null hypothesis that \mathbf{X} and \mathbf{Y} have the same distribution, i.e., $H_0 :$
432 $\mathbf{P}_1 = \mathbf{P}_2$.

433 1.1.2 Univariate case: The weighted Kolmogorov-Smirnov test

434 **The two-sample Kolmogorov-Smirnov test.** Consider the case where \mathbf{X}_i and \mathbf{Y}_j are scalar random
435 variables (i.e., $d = 1$). The associated empirical cumulative distribution functions (ECDFs) are denoted,
436 respectively, by $\mathbf{F}_{1,n}$ and $\mathbf{F}_{2,m}$. The univariate case occurs, for example, when there is only one lineage
437 in the trajectory(ies), so that the pseudotime estimates are scalars.

In this setting, one can test H_0 using the standard Kolmogorov-Smirnov test [19], with test statistic defined as:

$$\begin{aligned} \mathbf{D}_{n,m} &\equiv \sup_x |\mathbf{F}_{1,n}(x) - \mathbf{F}_{2,m}(x)| \\ &= \sup_{x \in \mathbf{X} \cup \mathbf{Y}} |\mathbf{F}_{1,n}(x) - \mathbf{F}_{2,m}(x)|. \end{aligned}$$

The rejection region at nominal level α is

$$\left[\sqrt{-\frac{1}{2} \times \log \frac{\alpha}{2} \times \frac{n+m}{n \times m}}, \infty \right).$$

438 That is, we reject the null hypothesis at the α -level if and only if $\mathbf{D}_{n,m} \geq \sqrt{-1/2 \times \log \alpha/2 \times \frac{n+m}{n \times m}}$.

The two-sample weighted Kolmogorov-Smirnov test. Consider a more general setting where we have weights $w_{1,i} \in [0, 1]$ and $w_{2,j} \in [0, 1]$ for each of the observations. In trajectory inference, the weights may denote the probability that a cell belongs to a particular lineage in the trajectory. Following Monahan [27], we modify the Kolmogorov-Smirnov test in two ways. Firstly, the empirical cumulative distribution functions are modified to account for the weights

$$\begin{aligned} \mathbf{F}_{1,n}(x) &= \frac{1}{\sum_{i=1}^n w_{1,i}} \sum_{i=1}^n w_{1,i} \times \mathcal{I}_{(-\infty, x]}(\mathbf{X}_i) \\ \mathbf{F}_{2,m}(x) &= \frac{1}{\sum_{j=1}^m w_{2,j}} \sum_{j=1}^m w_{2,j} \times \mathcal{I}_{(-\infty, x]}(\mathbf{Y}_j). \end{aligned}$$

Secondly, the definition of $\mathbf{D}_{n,m}$ is unchanged, but the significance threshold is updated, that is, the rejection region is

$$\left[\sqrt{-\frac{1}{2} \times \log \frac{\alpha}{2} \times \frac{n' + m'}{n' \times m'}}, \infty \right),$$

where

$$n' = \frac{\left(\sum_{i=1}^n w_{1,i} \right)^2}{\sum_{i=1}^n w_{1,i}^2} \quad \text{and} \quad m' = \frac{\left(\sum_{j=1}^m w_{2,j} \right)^2}{\sum_{j=1}^m w_{2,j}^2}.$$

439 **1.1.3 Multivariate case: The classifier test**

440 **Concept.** Suppose that we have a classifier $\delta(\cdot)$, which could be, for example, a multinomial regression
 441 or SVM classifier. This classifier is a function from the support of \mathbf{X} and \mathbf{Y} into $\{1, 2\}$. The data are
 442 first split into a learning and a test set, such that the test set contains n_{test} observations, equally-drawn
 443 from each population, i.e., there are $n_{\text{test}}/2$ observations $\mathbf{X}^{(\text{test})}$ from \mathbf{X} and $n_{\text{test}}/2$ observations $\mathbf{Y}^{(\text{test})}$
 444 from \mathbf{Y} . Next, the classifier is trained on the learning set. We denote by $Acc \equiv |\{i : \delta(\mathbf{X}_i^{(\text{test})}) = 1\} \cup \{j :$
 445 $\delta(\mathbf{Y}_j^{(\text{test})}) = 2\}|$ the number of correct assignments made by the classifier on the test set.

If $n = m$, under the null hypothesis of identical distributions, no classifier will be able to perform better on the test set than a random assignment would, i.e., where the predicted label is a *Bernoulli*(1/2) random variable. Therefore, testing the equality of the distributions of \mathbf{X} and \mathbf{Y} can be formulated as testing

$$H_0 : \mathbb{E}[Acc] = \frac{n_{\text{test}}}{2} \text{ vs. } H_1 : \mathbb{E}[Acc] > \frac{n_{\text{test}}}{2}.$$

Under the null hypothesis, the distribution of Acc is:

$$Acc \sim_{H_0} \text{Binom}(n_{\text{test}}, 1/2).$$

446 As detailed in Lopez-Paz and Oquab [20], one can use the classifier to devise a test that will guarantee
 447 the control of the Type 1 error rate.

448 **The classifier test in practice.** In practice, we make no assumptions about the way in which the
 449 distributions we want to compare might differ, which means the classifier needs to be quite flexible.
 450 Following Lopez-Paz and Oquab [20], we chose to use either a k -nearest neighbor classifier (k -NN) or
 451 a random forests classifier [28], since such classifiers are fast and flexible. Hyper-paramters are chosen
 452 through cross-validation on the learning set. To avoid issues with class imbalance, we downsample the
 453 distribution with the largest number of samples first so that each distribution has the same number of
 454 observations. That is, we have $n' = \min(m, n)$ observations in each condition (or class). A fraction (by
 455 default 30%, user-defined) is kept as test data, so that $n_{\text{test}} = .3 \times n'$. We then train the classifier on the
 456 learning data, and select the tuning parameters through cross-validation on that learning set. Finally, we
 457 predict the labels on the test set and compute the accuracy of the classifier on that test set. This yields
 458 our classifier test statistic.

459 **Power of the classifier test.** It is interesting to note that the classifier test is valid no matter the
 460 classifier chosen. However, the choice of classifier will have obvious impact on the power of the test.

461 **1.1.4 Multivariate case: Other methods**

462 Although we have found that the classifier test performs best in practice, there are many methods that
 463 test for the equality of two multivariate distributions. We have implemented a few such methods in
 464 `condiments`, in case users would like to try them: The two-sample kernel test [29] and the permutation
 465 test relying on the Wasserstein distance (see descriptions in the [supplementary methods](#)).

466 **1.1.5 Extending the setting by considering more than two conditions**

467 Consider $C \geq 2$ sets of samples, such that, for $c \in \{1, \dots, C\}$, we have n_c i.i.d. observations $\mathbf{X}^{(c)}$ with
 468 $\mathbf{X}_i^{(c)} \sim \mathbf{P}_c$. We want to test the null hypothesis:

$$H_0 : \mathbf{P}_{c_1} = \mathbf{P}_{c_2}, \forall c_1, c_2 \in \{1, \dots, C\} \text{ and } c_1 \neq c_2.$$

469 While extensions of the Kolmogorov-Smirnov test [30] and the two-sample kernel test [31] have been
 470 proposed, we choose to focus only on the framework that is most easily extended to C conditions, namely,
 471 the classifier test. Indeed, the C -condition classifier test requires choosing a multiple-class classifier
 472 instead of a binary classifier (which is the case for the k -NN classifier and random forests), selecting
 473 n_{test}/C observations for each class in the test set, and testing:

$$H_0 : \mathbf{E}[Acc] = \frac{n_{\text{test}}}{C} \text{ vs. } H_1 : \mathbf{E}[Acc] > \frac{n_{\text{test}}}{C}.$$

Under the null distributions, the distribution of Acc is:

$$Acc \sim_{H_0} \text{Binom}(n_{\text{test}}, 1/C).$$

474 **1.1.6 Extending the setting by considering an effect size**

Effect size for the Kolmogorov-Smirnov test. The null hypothesis of the (weighted) Kolmogorov-Smirnov test is $H_0 : P_1 = P_2$. We can modify this null hypothesis by considering an effect size threshold t , such that $H_0(t) : \sup_x |P_1(x) - P_2(x)| \leq t$. The test statistic is then modified as:

$$\mathbf{D}'_{n,m} \equiv \max(\mathbf{D}_{n,m} - t, 0)$$

475 and the remainder of the testing procedure is left unchanged.

Effect size for the classifier test. Similarly, the null and alternative hypotheses of the classifier test can be modified to test against an effect size threshold t as follows

$$H_0 : Acc \leq \frac{n_{\text{test}}}{C} + t \text{ vs. } H_1 : Acc > \frac{n_{\text{test}}}{C} + t.$$

476 **1.2 General statistical model for the trajectories**

477 Consider a set of condition labels $c \in \{1, \dots, C\}$ (e.g., “treatment” or “control”, “knock-out” or “wild-
478 type”). For each condition, there is a given topology/trajectory \mathcal{T}_c that underlies the developmental
479 process. This topology is generally in the form of a tree, with a starting state which then differentiates
480 along one or more lineages; but one can also have a circular graph, e.g., for the cell cycle. In general, a
481 trajectory is defined as a directed graph.

482 We denote by L_c the number of unique paths – or lineages – in the trajectory \mathcal{T}_c and by \mathcal{C}_c the set of
483 cells that belong to condition c . For example, for a tree structure, paths go from the root node (stem cell
484 type) to the leaf nodes (differentiated cell type). For a cell cycle, any node can be used as the start.
485 A cell i from condition c_i is characterized by the following features:

$$\begin{aligned} \mathbf{T}_i \sim G_{c_i} & & : \text{A vector of pseudotimes, one per lineage of } \mathcal{T}_{c_i} \\ \mathbf{W}_i \sim H_{c_i} & & : \text{A vector of weights, one per lineage of } \mathcal{T}_{c_i}, \text{ s.t. } \|\mathbf{W}_i\|_1 = 1. \end{aligned}$$

486 Note that the distribution functions are condition-specific. We further make the following assumptions:

- 487 • All G_c and H_c distributions are continuous;
- 488 • The support of all G_c is bounded in \mathbb{R}^{L_c} ;
- 489 • The support of all H_c is $[0, 1]^{L_c}$.

490 The gene expression model will be discussed below, in [the differential expression](#) section.

491 **Trajectory inference.** Many algorithms have been developed to estimate lineages from single-cell
492 data [5]. Most algorithms provide a binary indicator of lineage assignment, that is, the \mathbf{W}_i vectors are
493 composed of 0s and 1s, so that a cell either belongs to a lineage or it does not (note that when cells fall
494 along a lineage prior to a branching event, this vector may include multiple 1s, violating our constraint
495 that the \mathbf{W}_i have unit norm. In such cases, we normalize the weights to sum to 1).

496 **Mapping between trajectories.** Many of the tests that we introduce below assume that the cells
497 from different conditions follow “similar” trajectories. In practice, this means that we either have a
498 common trajectory for all conditions or that there is a possible manual mapping from one lineage to
499 another. The term “mapping” is more rigorously defined as follows.

500 **Definition 1** *The trajectories $\{\mathcal{T}_c : c \in \{1, \dots, C\}\}$ have a mapping if and only if $\forall (c_1, c_2) \in$
501 $\{1, \dots, C\}^2$, \mathcal{T}_{c_1} and \mathcal{T}_{c_2} are isomorphic.*

502 If there is a mapping, this implies in particular that the number of lineages L_c per trajectory \mathcal{T}_c is
503 the same across all conditions c and we call this this value L . Since a graph is always isomorphic with
504 itself, a common trajectory is a special case of a situation where there is a mapping.

505 **Definition 2** *The trajectories $\{\mathcal{T}_c : c \in \{1, \dots, C\}\}$ have a partial mapping if and only if
506 $\forall (c_1, c_2) \in \{1, \dots, C\}^2$, there is a subgraph $\mathcal{T}'_{c_1} \subset \mathcal{T}_{c_1}$ and a subgraph $\mathcal{T}'_{c_2} \subset \mathcal{T}_{c_2}$ that are
507 isomorphic.*

508 Essentially, this means that the size of the changes induced by the various conditions do not disturb
509 the topology of the original trajectory *too much*. The above mathematical definitions aim to formalize
510 what *too much* is. Indeed, if the conditions lead to very drastic changes, it will be quite obvious that the
511 trajectories are different and comparing them will mostly be either non-informative or will not require a
512 complex framework. We aim to build a test that retains reasonable power in more subtle cases.

513 1.3 Differential topology

514 **Imbalance score.** Consider a set of n cells, with associated condition labels $c_i \in \{1, \dots, C\}$ and
515 coordinate vectors \mathbf{X}_i in d dimensions, usually corresponding to a reduced-dimensional representation of
516 the expression data obtained via PCA or UMAP[24, 32].

517 Let $\mathbf{p} = \{p_c\}_{c \in \{1, \dots, C\}}$ denote the “global” distribution of cell conditions, where p_c is the overall
518 proportion of cells with label c in the sample of size n . The imbalance score of a cell reflects the deviation
519 of the “local” distribution of conditions in a neighborhood of the cell compared to the global distribution
520 \mathbf{p} . Specifically, for each cell i , we compute its k -nearest neighbor graph using the Euclidean distance in
521 the reduced-dimensional space. We therefore have a set of k neighbors and a set of associated neighbor
522 condition labels $c_{i,\kappa}$ for $\kappa \in \{1, \dots, k\}$. We then assign to the cell a z -score, based on the multinomial
523 test statistic $P(\{c_{i,\kappa}\}_{\kappa \in \{1, \dots, k\}}, \mathbf{p})$, as defined in Section S-1.2. Finally, we smooth the z -scores in the
524 reduced-dimensional space by fitting s cubic splines for each dimension. The fitted values for each of the
525 cells are the imbalance scores. Thus, the imbalance scores rely on two user-defined parameters, k and s .
526 We set default values of 10 for both parameters. However, since this is meant to be an exploratory tool,
527 we encourage users try different values for these parameters and observe the changes to better understand
528 their data.

529 **General setting for the topologyTest.** The imbalance score only provides a qualitative visual in-
530 spection of local imbalances in the distribution of cell conditions. However, we need a more global and
531 formal way to test for differences in topology between condition-specific trajectories. That is, we wish to
532 test the null hypothesis

$$H_0 : \mathcal{T}_{c_1} = \mathcal{T}_{c_2}, \forall (c_1, c_2) \in \{1, \dots, C\}^2. \quad (8)$$

533 In practice, in order to test H_0 , we have a set of cells i with condition labels c_i . We can estimate the
534 pseudotimes of each cell when fitting a trajectory for each condition. We then want to compare this
535 distribution of pseudotimes to a null distribution. To generate this null distribution, we use permutations
536 in the following manner

- 537 a) Estimate \mathbf{T}_i for all i by inferring one trajectory per condition, using any trajectory inference method.
- 538 b) Randomly permute the condition labels c_i to obtain new labels c'_i , re-estimate \mathbf{T}'_i for each i .
- 539 c) Repeat the permutation r times (by default, $r = 100$).

540 Under the null hypothesis, the n \mathbf{T}_i should therefore be drawn from the same distribution as the $r \times n$
541 \mathbf{T}'_i . We can test this using the weighted Kolmogorov-Smirnov test (if $L = 1$), the kernel two-sample test
542 (if $C = 2$), or the classifier test (any C). This is the **topologyTest**.

543 The aforementioned tests require that the samples be independent between the two distributions
544 under comparison. However, here, the two distributions correspond to different pseudotime estimates for
545 the same cells so the samples are not independent between distributions. Even within distributions, the
546 independence assumption is violated: the pseudotimes are estimated using trajectory inference methods
547 that rely on all samples. Moreover, within the \mathbf{T}'_i , we have r pseudotime estimates of each cell.

548 The first two violations of the assumptions are hard to avoid and are further addressed in the [discussion](#)
549 section. However, we can eliminate the third one by simply taking the average \mathbf{T}'_i for each cell. We
550 then compare two distributions each with n samples. Both options (with and without averaging) are
551 implemented in the **condiments R** package, but the default is the average.

552 Furthermore, rather than attaching strong probabilistic interpretations to p -values (which, as in most
553 RNA-seq applications, would involve a variety of hard-to-verify assumptions and would not necessarily
554 add much value to the analysis), we view the p -values produced by the **condiments** workflow simply as
555 useful numerical summaries for exploring trajectories across conditions and identifying genes for further
556 inspection.

557 **Running the topologyTest in practice.** Under the null, there should exist a mapping between
558 trajectories, both within conditions and between permutations. However, in practice, most trajectory
559 inference methods will be too unstable to allow for automatic mapping between the runs. Indeed, they
560 might find a different number of lineages for some runs. Moreover, even if the number of lineages and
561 graph structure remained the same across all permutations, mapping between permutations would break
562 even more the independence assumption since the condition labels would need to be used.

563 Therefore, for now, the `topologyTest` test is limited to two trajectory inference methods, `slingshot` [2]
564 and `TSCAN` [4], where a set graph structure can be prespecified. Both methods rely on constructing
565 a minimum spanning tree (MST) on the centroids of input clusters in a reduced-dimensional space to
566 model branching lineages. In `TSCAN`, a cell’s pseudotime along a lineage is determined by its projection
567 onto a particular branch of the tree, and its weight of assignment is determined by its distance from the
568 branch. `slingshot` additionally fits simultaneous principal curves. A cell’s pseudotime along a lineage is
569 determined by its projection onto a particular curve and its weight of assignment is determined by its
570 distance from the curve. We therefore construct the MST on the full dataset (i.e., using all the cells
571 regardless of their condition label), based on user-defined cluster labels. Then, we keep the same graph
572 structure as input to either TI method: the nodes are the centers of the clusters, but restrained to cells
573 of a given condition. This way, the path and graph structure are preserved. Note however, that there no
574 guarantee that the graph remains the MST when it is used for TI on a subset of cells.

575 1.4 Testing for differential progression

576 The differential progression test requires that a (partial) mapping exists between trajectories. If the
577 mapping is only partial, we restrict ourselves to the mappable parts of the trajectories (i.e., subgraphs).

578 **Testing for differential progression for a single lineage.** For a given lineage l , we want to test
579 the null hypothesis that the pseudotimes along the lineage are identically distributed between conditions,
580 which we call *identical progression*. Following the above notation, we want to test that the l^{th} components
581 G_{lc} of the distribution functions G_c are identical across conditions

$$H_0 : G_{lc_1} = G_{lc_2}, \forall (c_1, c_2). \quad (9)$$

582 **Testing for global differential progression.** We can also test for global differences across all lineages,
583 that is,

$$H_0 : G_{c_1} = G_{c_2}, \forall (c_1, c_2). \quad (10)$$

584 **Possible tests.** If $C = 2$, all tests introduced in Section 1.1 can be used to test the hypothesis in
585 Equation (9). If $C > 2$, we need to rely on the classifier test.

586 If $L = 1$, the hypotheses in Equations (9) and (10) are identical. However, for $L > 1$, the functions
587 G_c are not univariate distributions.

588 **Using the Kolmogorov-Smirnov test in the $L > 1$ setting.** For $L > 1$, we can use lineage-level
589 weights as observational weights for each individual lineage, which is an appealing property. Two settings
590 are possible.

- 591 • Test the null hypothesis in Equation (9) for each lineage using the Kolmogorov-Smirnov test and
592 perform a global test using the classifier test or the kernel two-sample test.
- Test the null hypothesis in Equation (9) for each lineages using the Kolmogorov-Smirnov test and
combine the p -values p_l for each lineage l using Stouffer’s Z-score method [33], where each lineage
is associated with observational weights $W_l = \sum_{i=1}^n \mathbf{W}_i[l]$. The nominal p -value associated with
the global test is then

$$p_{glob} \equiv \frac{\sum_{l=1}^L W_l p_l}{\sqrt{\sum_{l=1}^L W_l^2}}.$$

593 Note that the second setting violates the assumption of Stouffer’s Z-score method, since the p -values
594 are not i.i.d. However, this violation does not seem to matter in practice and this test outperforms others
595 so we set it as default.

596 1.5 Testing for differential differentiation

597 The differential progression test requires that a (partial) mapping exists between trajectories. If the
598 mapping is only partial, we restrict ourselves to the mappable parts of the trajectories.

599 **Testing for differential differentiation for a single pair of lineages.** For a given pair of lineages
600 l, l' , we want to test the null hypothesis that the cells differentiate between l and l' in the same way
601 between all conditions, which we call *identical differentiation*. Following the above notation, we want to
602 test that the l^{th} and l'^{th} components of the distribution function H_c are the same

$$H_0 : \forall (c_1, c_2), [H_{lc_1}, H_{l'c_1}] = [H_{lc_2}, H_{l'c_2}]. \quad (11)$$

603 **Testing for global differential differentiation.** We can also test for a global difference across all
604 pairs of lineages, that is,

$$H_0 : \forall (c_1, c_2), H_{c_1} = H_{c_2} \quad (12)$$

605 **Possible tests.** Since all variables are multivariate, we cannot use the Kolmogorov-Smirnov test. By
606 default, this test relies on the classifier test with random forest as a classifier.

607 1.6 Testing for differential expression

Notation. The gene expression model does not require a mapping or even a partial mapping. Indeed,
it can work as well with a common trajectory, different trajectories, or even a mix where some lineages
can be mapped between the trajectories for various conditions and others cannot. To reflect this, we
consider all L_{tot} lineages together. We introduce a new weight for each cell

$$\mathbf{Z}_i = \{Z_{ilc}\}_{l \in \{1, \dots, L_{tot}\}, c \in \{1, \dots, C\}} \text{ s.t. } \begin{cases} Z_{ilc} = 0, & \text{if } i \neq C_c \text{ or } l \notin \mathcal{T}_{c_i} \\ \{Z_{ilc_i}\}_{l \in \{1, \dots, C\}} \sim \mathcal{M}(\mathbf{W}_i), & \text{otherwise} \end{cases},$$

608 where $\mathcal{M}(\mathbf{W}_i)$ is a binary (or one-hot) encoding representation of a multinomial distribution with pro-
609 portions \mathbf{W}_i as in `tradeSeq`.

Likewise, we modify the pseudotime vector to have length L_{tot} such that

$$T_{li} = \begin{cases} 0, & \text{if } l \notin \mathcal{T}_{c_i} \\ \mathbf{T}_i[l], & \text{otherwise} \end{cases}.$$

610 **Gene expression model.** We adapt the model from Van den Berge et al. [8] to allow for condition-
611 specific expression. For a given gene j , the expression measure Y_{ji} for that gene in cell i can be modeled
612 thus:

$$\begin{cases} Y_{ji} & \sim NB(\mu_{ji}, \phi_j) \\ \log(\mu_{ji}) & = \eta_{ji} \\ \eta_{ji} & = \sum_{l=1}^{L_{tot}} \sum_{c=1}^C s_{jlc}(T_{li}) Z_{ilc} + \mathbf{U}_i \boldsymbol{\alpha}_j + \log(N_i) \end{cases}, \quad (13)$$

613 where the mean μ_{ji} of the negative binomial distribution is linked to the additive predictor η_{ji} using
614 a logarithmic link function. The \mathbf{U} matrix represents an additional design matrix, representing, for
615 example, a batch effect.

616 The model relies on lineage-specific, gene-specific, and condition-specific smoothers s_{jlc} , which are
617 linear combinations of K cubic basis functions, $s_{jlc}(t) = \sum_{k=1}^K b_k(t) \beta_{jlc k}$.

618 **Testing for differential Expression.** With this notation, we can introduce the `conditionTest`,
619 which, for a given gene j , tests the null hypothesis that the smoothers are identical across conditions:

$$H_0 : \forall (c_1, c_2), \forall k, \forall l, \beta_{jlc_1 k} = \beta_{jlc_2 k}. \quad (14)$$

620 We fit the model using the `mgcv` package [34] and test the null hypothesis using a Wald test for
621 each gene. Note that, although the gene expression model can be fitted without any mapping, the
622 `conditionTest` only exists for lineages with at least a mapping for two conditions.

1.7 Simulation study

1.7.1 Simulating datasets

The simulation study relies on the `dyngen` framework of Cannoodt et al. [22] and all datasets are simulated as follows. 1/ A common trajectory is generated, with an underlying gene network that drives the differentiation along the trajectory. 2/ A set of N_{WT} cells belonging to the wild-type condition (i.e., with no modification of the gene network) is generated. 3/ One master regulator that drives differentiation into one of the lineages is impacted, by multiplying the wild-type expression rate of that gene by a factor m . If $m = 1$, there is no effect; if $m > 1$, the gene is over-expressed; and if $m < 1$, the gene is under-expressed, with $m = 0$ amounting to a total knock-out. 4/ A set of $N_{KO} = N_{WT}$ cells is generated using the common trajectory with the modified gene network. 5/ A common reduced-dimensional representation is computed.

We generate three types of datasets, over a range of values of m : a simple trajectory with $L = 2$ lineages and $C = 2$ conditions (WT and KO) named \mathcal{T}_1 ; a trajectory with two consecutive branchings with $L = 3$ lineages and $C = 2$ conditions (WT and KO) named \mathcal{T}_2 ; and a simple trajectory with $L = 2$ lineages and $C = 3$ conditions (WT, KO, and UP) named \mathcal{T}_3 . For the latter case, Steps 3-4/ are repeated twice, with values of m for KO and $1/m$ for UP.

For \mathcal{T}_1 and \mathcal{T}_2 , we use values of $m \in \{.5, .8, .9, .95, 1, 1/.95, 1/.9, 1/.8, 1/.5\}$, such that at the extremes the KO cells fully ignore some lineages. Values of .95 and $1/.95$ represent the closest to no condition effect ($m = 1$), where the effect was still picked out by some tests. For \mathcal{T}_3 , since the simulation is symmetrical in m , we pick $m \in \{.5, .8, .9, .95, 1\}$. We have one large dataset per value of m and per trajectory type. We use those large datasets to generate smaller ones of size n , by sampling 10% of the cells from each condition 50 times and applying the various tests on the smaller datasets. The reason for first generating a large dataset and then smaller ones by subsampling instead of generating small ones straightaway are computational: the generation of the datasets is time-consuming and the part that scales with N_{WT} can be parallelized. Hence, it is almost as fast to generate a large dataset than a small one with `dyngen`. We pick $N_{WT} = 20,000$ (for the large dataset) and thus $n = 2,000$.

Since we generate many datasets with true effect ($m \neq 1$) but only one null dataset, the size of N_{WT} for $m = 1$ is doubled to 40,000. To be comparable, the fraction of cells sampled is decreased to 5% so that $n = 2,000$ and we perform 100 subsampling. Table 2 recapitulates all this.

Table 2: *Summary of all simulated datasets.* We report the name, number of cells n_{WT} for values of $m \neq 1$ and $m = 1$, number of conditions C , number of lineages L , impacted master regulator, and figure numbers for the associated gene network and an example of low-dimensional representation.

Dataset	N_{WT}		n	L	C	Impacted Regulator	Gene Network Figure	Reduced Dimension Representation
	$m \neq 1$	$m = 1$						
\mathcal{T}_1	20,000	40,000	2,000	2	2	B3	Fig S1a	Fig.2a
\mathcal{T}_2	20,000	40,000	2,000	3	2	D2	Fig S1b	Fig.2b
\mathcal{T}_3	20,000	40,000	2,000	2	3	B3	Fig S1a	Fig.2c

1.7.2 Measuring the performance of the tests on the simulated datasets

To run the `condiments` workflow, we first estimate the trajectories using `slingshot` with the clusters provided by `dyngen`. Then, we run the `progressionTest` and the `differentiationTest` with default arguments.

We compare `condiments` to two other methods. `milo` [16] and `DAseq`[17] both look at differences in proportions within local neighborhoods, using k -nearest neighbor graphs to define this locality. Then, `milo` uses a negative binomial GLM to compare counts for each neighborhood, while `DAseq` uses a logistic classifier test. Therefore, both methods test for differential abundance in multiple regions. To account for multiple testing, we adjust the p -values using the Benjamini, Yoav ; Hochberg [21] FDR-controlling procedure.

We select two adjusted p -value cutoffs, .01 and .05, which amount to controlling the FDR at nominal level 1% and 5%, respectively. For a given cutoff c and a given dataset, we can look at the results of each test on all simulated datasets for all values of m . For each test, the number of true positives (TP) is the number of simulated datasets where $m \neq 1$ and the adjusted p -value is smaller than c , the number of true negatives (TN) is the number of simulated datasets where $m = 1$ and the adjusted p -value is larger than c , the number of false positives (FP) is the number of simulated datasets where $m = 1$ and the adjusted p -value is smaller than c , and the number of false negatives (FN) is the number of subsampled datasets

668 where $m \neq 1$ and the adjusted p -value is larger than c . We then examine 5 metrics built on these four
669 variables:

$$\begin{aligned}\text{True Negative Rate (TNR)} &= \frac{TN}{TN + FP} \\ \text{True Positive Rate (TPR)} &= \frac{TP}{TP + FN} \\ \text{Positive Predictive Value (PPV)} &= \frac{TP}{TP + FP} \\ \text{Negative Predictive Value (NPV)} &= \frac{TN}{TN + FN} \\ \text{F1-score} &= 2 \frac{PPV \times TPR}{PPV + TPR}.\end{aligned}$$

808 S-1 Supplementary methods

809 S-1.1 Other methods implemented in the **condiments** package to test equality 810 of distributions

811 These methods were found to be less efficient in initial benchmarking, but are implemented in case users
812 want to use them.

813 S-1.1.1 Multivariate case: The two-sample kernel test

Mean maximum discrepancy. The two-sample kernel test was defined by Gretton et al. [29] and relies on the mean maximum discrepancy (MMD). Considering a kernel function

$$k : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R} \\ (x, y) \mapsto k(x, y)$$

the MMD is then defined as

$$MMD^2(\mathbf{P}_1, \mathbf{P}_2, k) \equiv \mathbb{E}_{\mathbf{P}_1, \mathbf{P}_1}[k(X, X')] + \mathbb{E}_{\mathbf{P}_2, \mathbf{P}_2}[k(Y, Y')] - 2\mathbb{E}_{\mathbf{P}_1, \mathbf{P}_2}[k(X, Y)].$$

814 For a properly defined kernel, we have $MMD^2(\mathbf{P}_1, \mathbf{P}_2, k) = 0$ i.i.f. $\mathbf{P}_1 = \mathbf{P}_2$.

815 **Unbiased statistic.** Following Gretton et al. [29], we define the unbiased MMD statistic:

$$MMD_u^2(\mathbf{X}, \mathbf{Y}) \equiv \frac{1}{n(n-1)} \sum_{i=1}^n \sum_{j \neq i}^n k(\mathbf{X}_i, \mathbf{X}_j) + \frac{1}{m(m-1)} \sum_{i=1}^m \sum_{j \neq i}^m k(\mathbf{Y}_i, \mathbf{Y}_j) - \frac{2}{mn} \sum_{i=1}^n \sum_{j=1}^m k(\mathbf{X}_i, \mathbf{Y}_j).$$

816 **Linear statistic for faster computations.** While the MMD^2 offers fast convergence, it can be
817 burdensome to compute when m and n get large. Gretton et al. [29] propose a linear statistic in the case
818 $m = n$. We can extend this in the general setting by just sampling a fixed fraction of the terms of each
819 sum. This lowers kernel computation costs drastically.

820 **Null distribution of the statistic.** For some kernels, the MMD_u^2 follows some theoretical inequalities
821 under the null that allows one to define rejection regions. However, this is not always the case. Therefore,
822 in practice, we instead rely on permutations to compute a null distribution for the test statistic. Under
823 the null, \mathbf{X}_i and \mathbf{Y}_j are from the same distribution so they can be swapped in the sums. We can therefore
824 generate an empirical distribution and use it to define rejection regions.

825 S-1.1.2 Multivariate case: Optimal transport

826 We consider the Wasserstein distance [35, 36], also known as earth's mover distance, between the two
827 distributions, estimated using the samples \mathbf{X} and \mathbf{Y} . We can generate a null distribution for this metric
828 by permuting observations in the combined \mathbf{X} and \mathbf{Y} datasets, thereby obtaining a valid test for $H_0 : \mathbf{P}_1 = \mathbf{P}_2$. This works in any number of dimensions, but is limited to the two-sample case.

830 S-1.2 Multinomial test

We consider a set of categories arbitrarily numbered from 1 to C . Additionally, we consider a null distribution \mathbf{C}_0 , defined on 1 to C by a vector of probabilities $\mathbf{p} = \{p_c\}_{c=1}^C$. Then, given a set of n i.i.d. realizations $(c(1), \dots, c(n))$ of a random variable \mathbf{C} , we can test the null hypothesis $H_0 : \mathbf{C} \sim \mathbf{C}_0$ or, equivalently, $H_0 : \mathbf{P}(\mathbf{C} = c) = p_c, \forall c \in \{1, \dots, C\}$. Under the null, $\mathbf{P}(c_i) = p_{c_i}$ and the associated p -value of the multinomial test can be defined as:

$$P(x, \mathbf{p}) = \sum_{y \in \{1, \dots, C\}^n : \mathbf{P}_{H_0}(y) \leq \mathbf{P}_{H_0}(x)} \mathbf{P}_{H_0}(y).$$

831 It verifies: $\forall \alpha \in [0 : 1], \mathbf{P}_{H_0}(P(x, \mathbf{p}) \leq \alpha) \leq \alpha$.

832 S-1.3 Case studies: Processing.

833 **TGFB.** The two conditions are normalized separately using `SCTransform` [37] and then integrated
834 using `Seurat` [38]. The reduced-dimensional representation is computed using `UMAP` [24] on the top 50
835 principal components (PC). The imbalance score is computed with parameters $k = 20$ and $smooth = 40$.
836 The trajectory is estimated using `slingshot`. The `topologyTest` is run with 100 permutations with the
837 Kolmogorov-Smirnov test and default threshold of .01. The `progressionTest` is run with defaults. All
838 genes with at least 2 reads in 15 cells are kept. The smoothers are fitted for each gene using 7 knots
839 as recommended by the `evaluateK` function. Gene set enrichment analysis is done using the `fgsea` [39]
840 package on the GO Biological Process ontology sets.

841 **TCCD.** The dataset is first filtered using the cell type assignments from the original publication to only
842 retains cells labelled as hepatocytes. The count matrix is scaled using `Seurat` [38] and reduced-dimensional
843 coordinates are computed using `UMAP` [24] on the top 30 PCs. The imbalance score is computed with
844 default k and $smooth = 5$. The trajectory is estimated using `slingshot`. The `topologyTest` is run with
845 100 permutations with the Kolmogorov-Smirnov test and default threshold of .01. The `progressionTest`
846 is run with defaults. All genes with at least 2 reads in 15 cells are kept; all genes with at least 3 reads in
847 10 cells are kept. The smoothers are fitted for each gene using 7 knots as recommended by the `evaluateK`
848 function.

849 **KRAS.** The reduced-dimensional coordinates were obtained from the original publication. The im-
850 balance score is run with defaults and the `topologyTest` is run with 100 permutations with the clas-
851 sifier test and default threshold of .01. The trajectories are estimated using `slingshot` with parameters
852 $reweight = FALSE$ and $reassign = FALSE$. The `progressionTest` and `differentiationTest` are
853 run with defaults. All genes with at least 5 reads in 10 cells are kept. The smoothers are fitted for each
854 gene using 6 knots as recommended by the `evaluateK` function.

855 **S-2** Supplementary figures

856 **S-2.1** Simulations

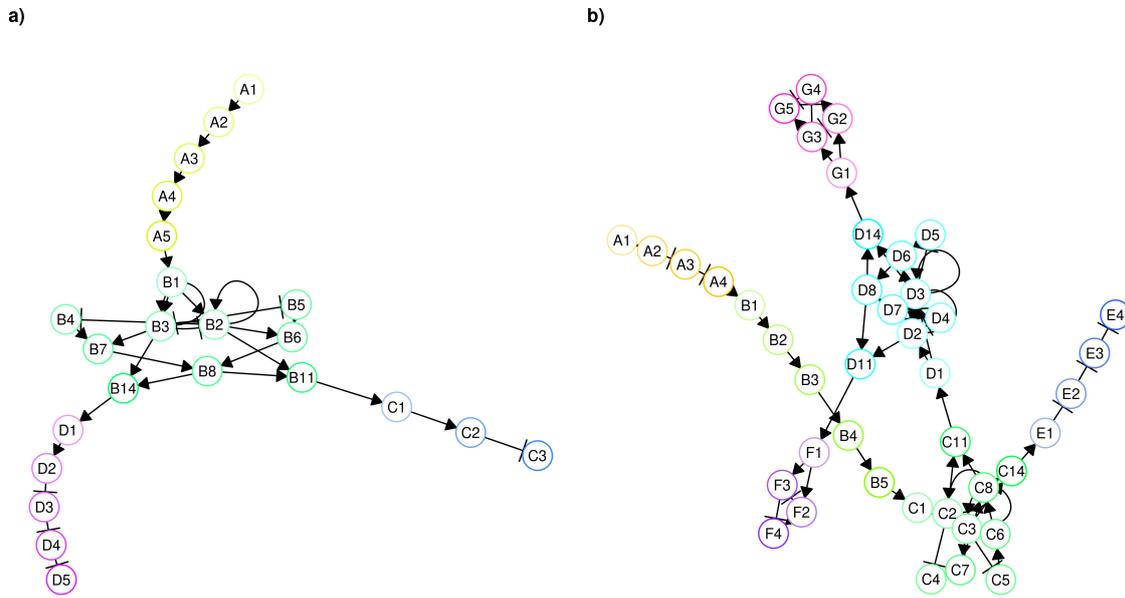

Figure S1: *Simulation example.* Regulator networks for the (a.) two-lineage and (b.) three-lineage trajectories.

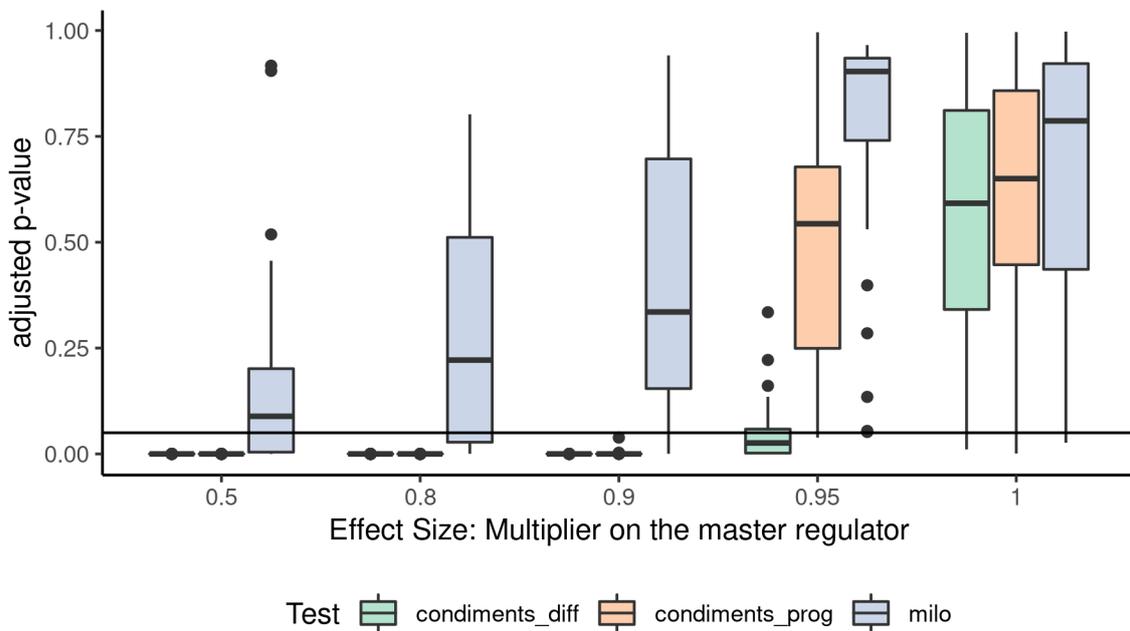

Figure S2: *Results on the third type of dataset.* For all values of $m \in \{.5, .8, .9, .95, 1\}$, we generate null datasets with two lineages and three conditions and we compute the adjusted p -values of all tests that can handle 3 conditions. The distributions of p -values are then displayed. $m = 1$ is negative (no effect), while $m < 1$ is positive (some effect) with smaller values (toward the left) representing stronger effect.

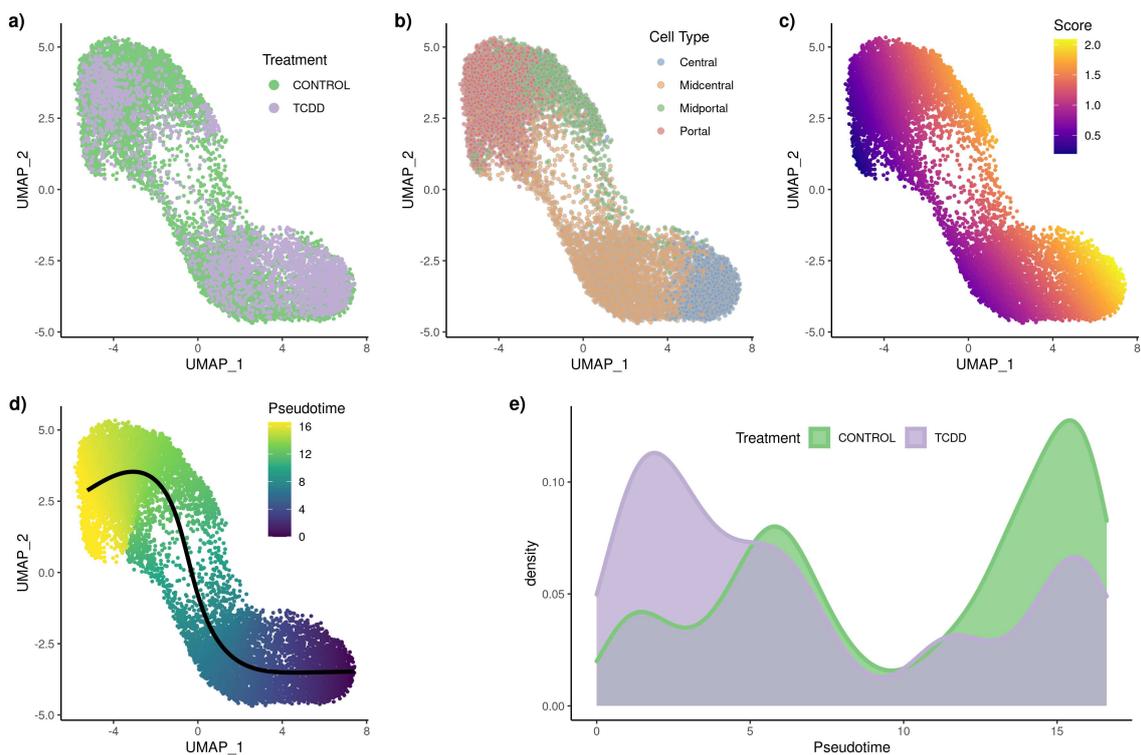

Figure S3: *TCDD* dataset: *Differential topology and differential progression*. After normalization and projection on a reduced-dimensional space, the cells can be represented, colored either by treatment label (a.), cell type (b.), or batch (c.). Using the treatment label and the reduced-dimensional coordinates, an imbalance score is computed and displayed (d.). The `diffTopoTest` rejects the null and separate trajectories are fitted for each condition (e.). After mapping the lineages, there is also differential progression: the pseudotime distribution along the trajectory are not identical (f.) and we indeed reject the null using the `diffProgressionTest`.

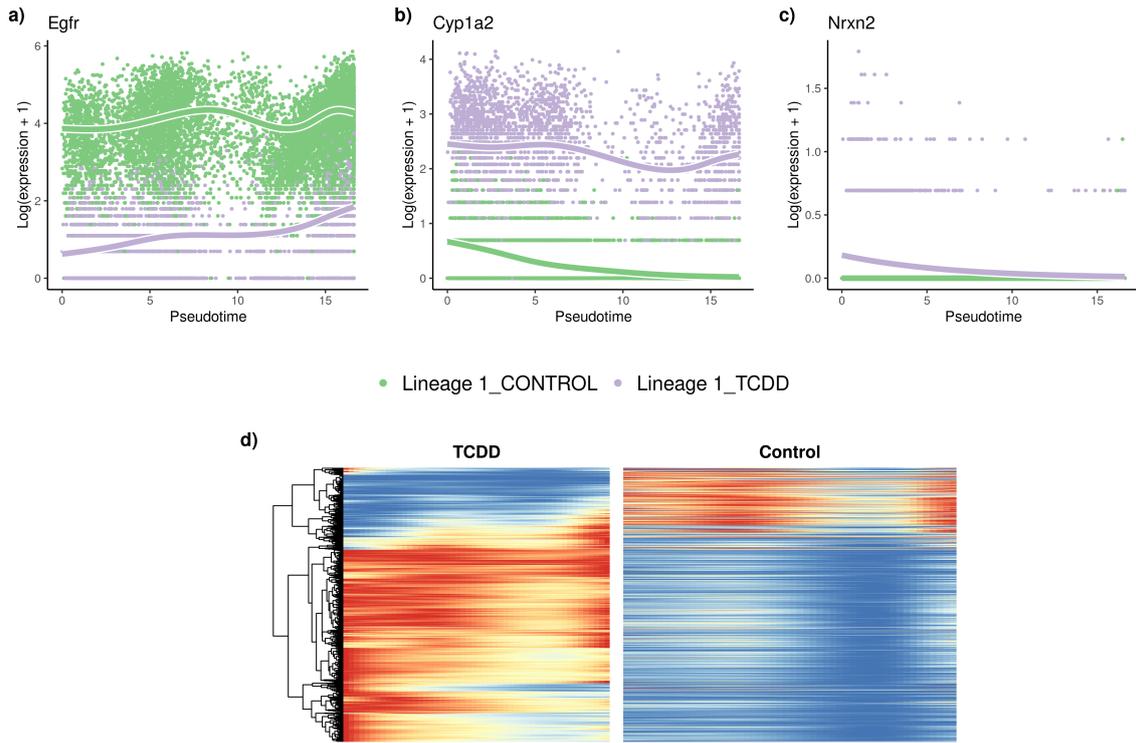

Figure S4: *TCDD* dataset: *Differential expression*. The tradeSeq gene expression model is fitted using the trajectory computed with slingshot. Differential expression between conditions is assessed using the `conditionTest` and genes are ranked according to the test statistics. The genes with the highest (a.), second highest (b.), and smallest (c.) test statistics are displayed. After adjusting the p -values to control the FDR at a nominal level of 5%, we display genes in both conditions using a pseudocolor image (d.).

858 S-2.3 KRAS

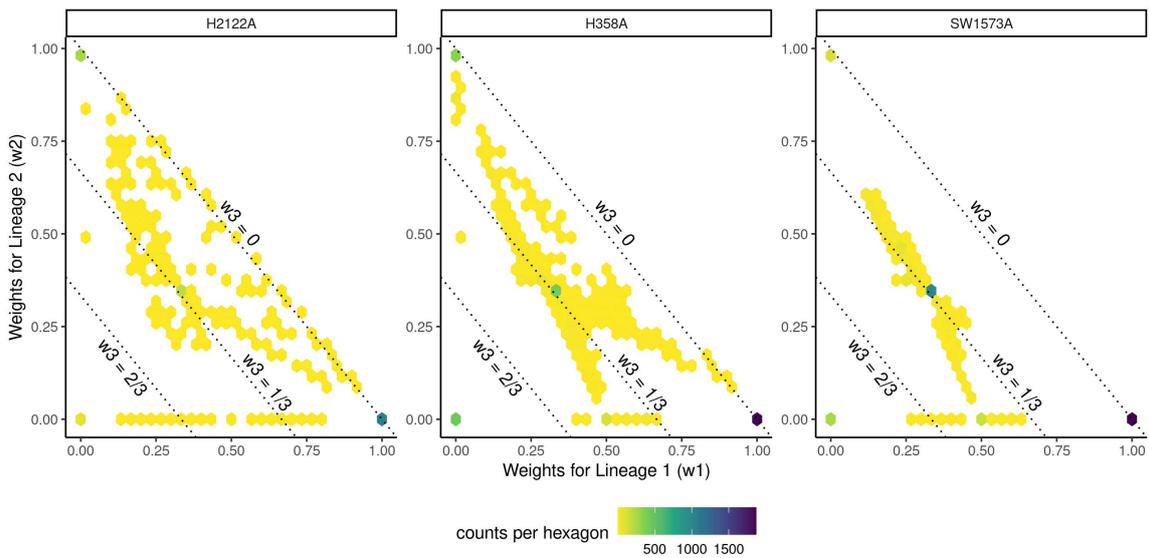

Figure S5: *KRAS* dataset: *Differential differentiation*.

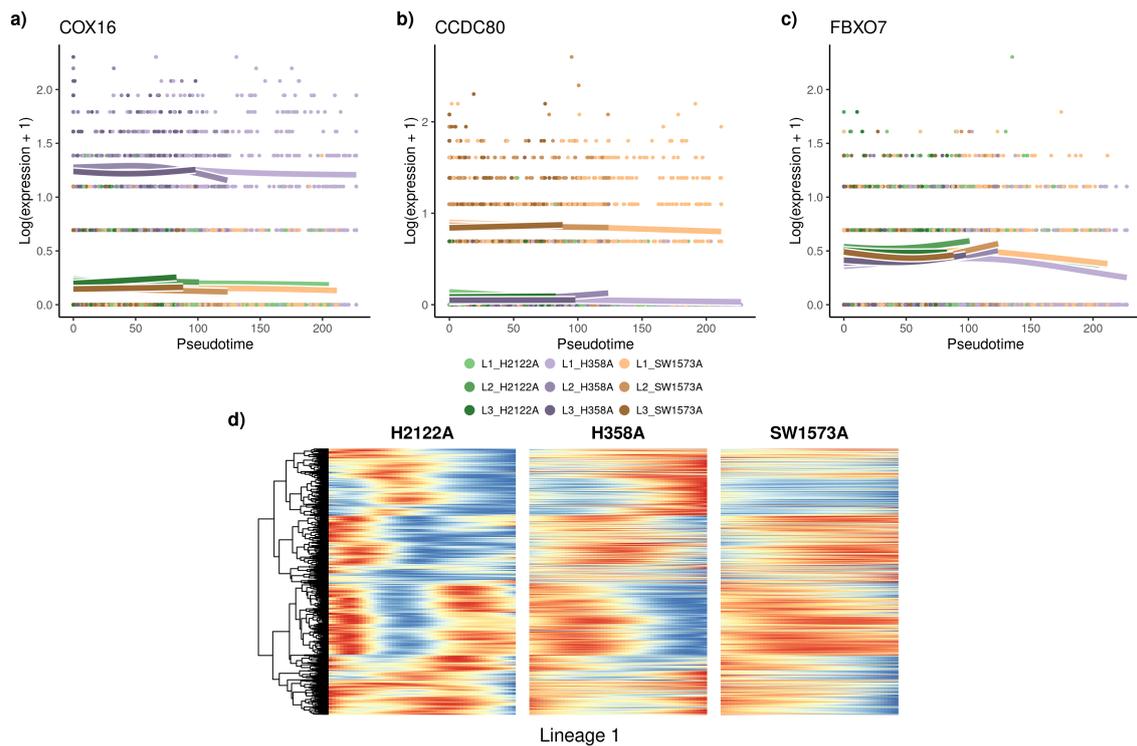

Figure S6: *KRAS* dataset: *Differential expression*. The tradeSeq gene expression model is fitted using the trajectory computed with slingshot. Differential expression between conditions is assessed using the `conditionTest` and genes are ranked according to the test statistics. The genes with the highest (a.), second highest (b.), and smallest (c.) test statistics are displayed. Focusing on the first lineage, we select all differentially expressed genes in that lineage after adjusting the p -values to control the FDR at a nominal level of 5%. We display the genes for all three conditions using a pseudocolor image (d.) along this first lineage.

Figures

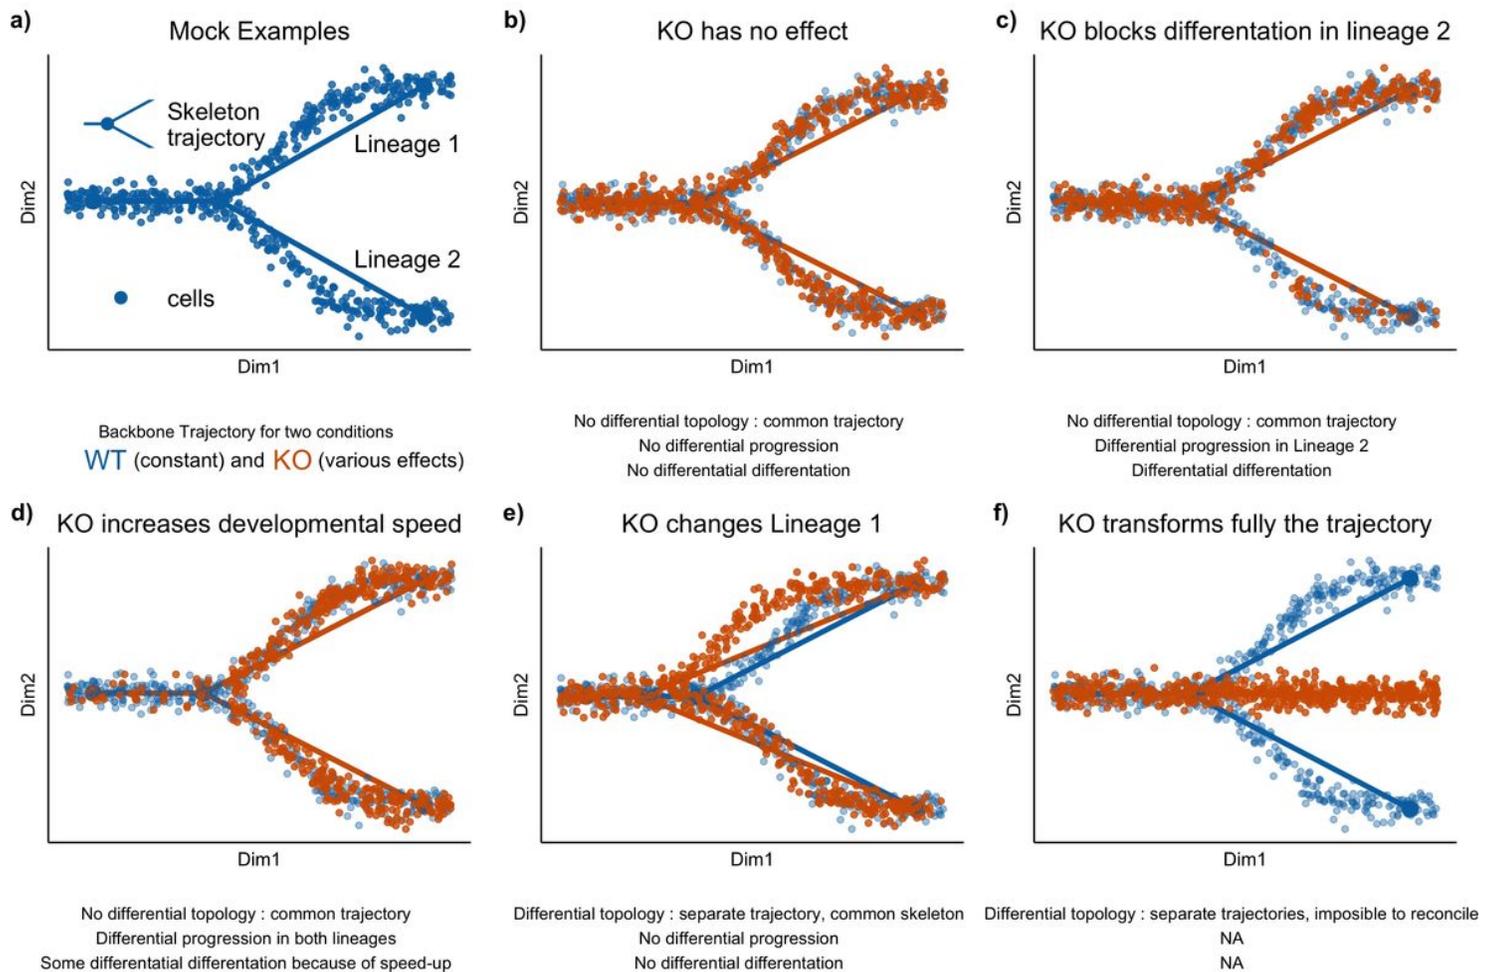

Figure 1

Illustrating the first two steps of the conditions work on with several scenarios (a.) The examples are all built on a similar wild-type backbone, i.e., two lineages that slowly diverge in the absence of knocking out. Cells either originate from a wild-type (WT, blue) or a knock-out (KO, orange) condition. In (b.), the knock-out has no effect, all three tests fail to reject their null hypothesis. In (c.), the knock-out partly blocks differentiation along Lineage 2, meaning that fewer cells develop along that lineage. In this case, while the topologyTest fails to reject the null, we have both differential progression along Lineage 2 and differential differentiation. In (d.), the knock-out speeds development, so there are more orange cells toward the end of both lineages. This leads to both differential progression and differentiation. In (e.), the knock-out modifies the intermediate stage for Lineage 1 and changes where the lineages bifurcate; based on the topologyTest, we fit one trajectory per condition. However, the skeleton structure is unchanged, so there is a mapping between the two trajectories and we can still test for differential progression and differentiation. In both cases, we fail to reject the null. Finally, in (f.), the knock-out fully disrupts the developmental process: all cells in the knock-out condition progress along a new lineage.

Here, we fit separate trajectories and these cannot be reconciled easily, so we cannot proceed to Steps 2 and 3.

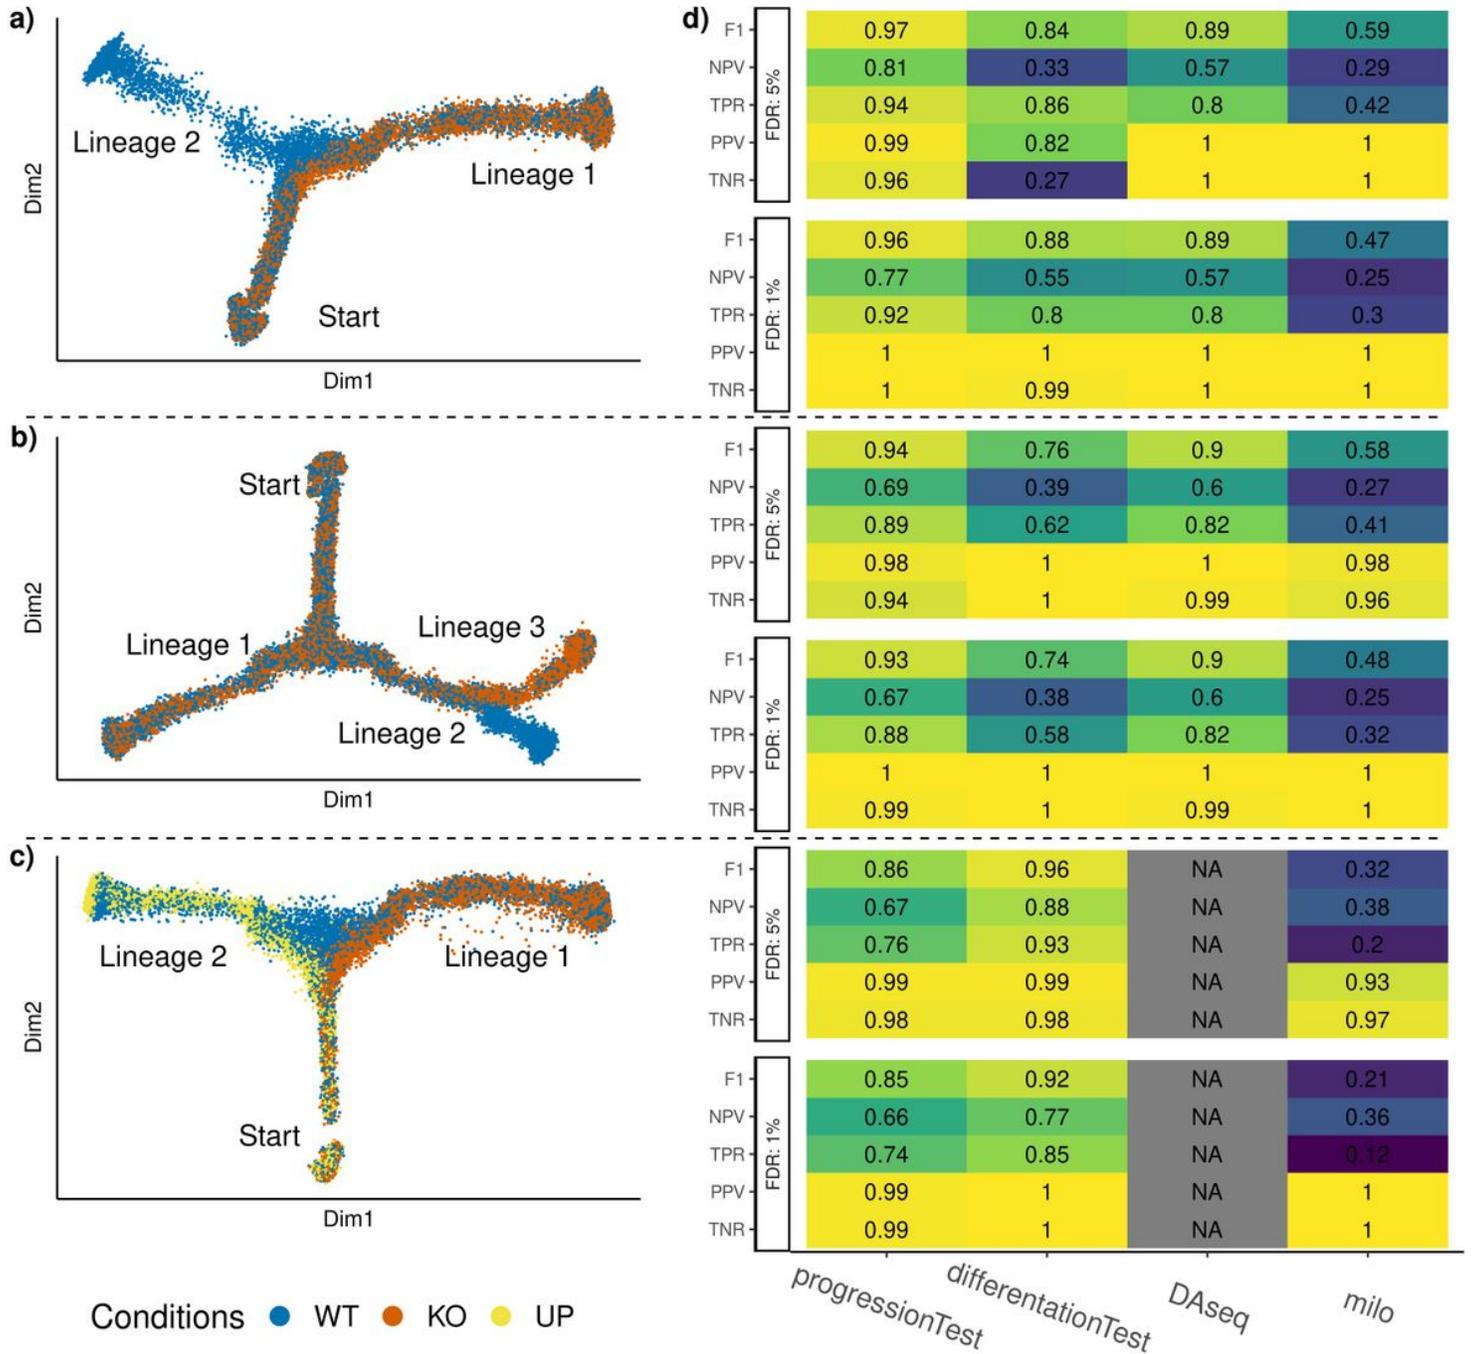

Figure 2

Simulation results. Three types of datasets are generated, with respectively two, three, and two lineages, and two, two, and three conditions. Reduced-dimensional representations of these datasets, for a multiplier value of $m = :5$, are presented in (a.), (b.), and (c.), respectively. After generating multiple versions of the datasets for a range of values of m , we compare the performance of the progressionTest and differentiationTest with that of Daseq[17] and milo[16], when controlling the false discovery rate at nominal levels 1% and 5% using the Benjamini-Hochberg [21] procedure. In (d.), each cell represents the

performance measure associated with one test on one dataset for one nominal FDR level. Cells are also colored according to the performance. Overall, with two conditions, the progressionTest ranks first, followed by DAsseq and the differentiationTest. With three conditions, the differentiationTest ranks first. DAsseq is limited to two conditions. Exact simulation parameters and metrics are specified in the Methods section.

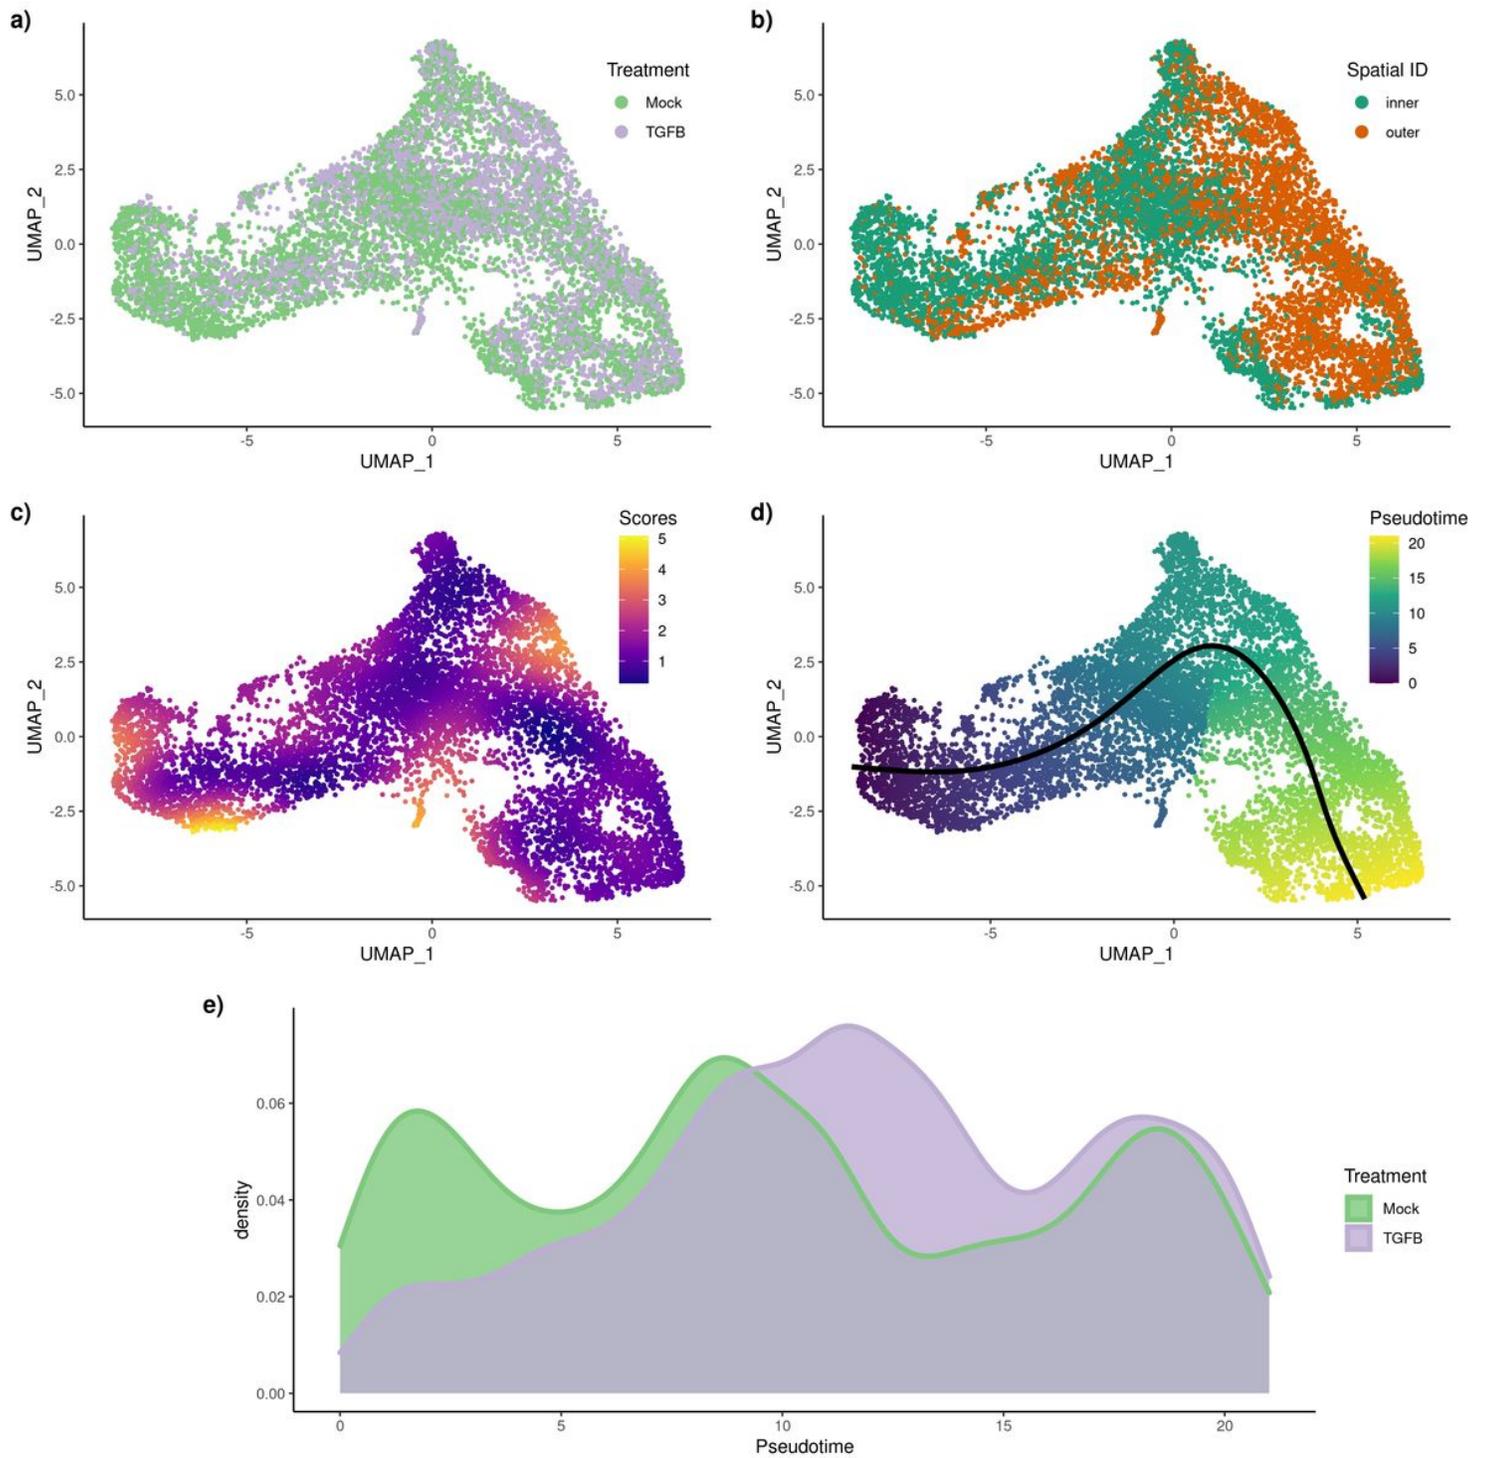

Figure 3

TGFB dataset: Differential topology and differential progression. After normalization and projection on a reduced-dimensional space (using UMAP), the cells can be colored either by treatment label (a.) or spatial origin (b.). Using the treatment label and the reduced-dimensional coordinates, an imbalance score is computed and displayed (c.). The topologyTest fails to reject the null hypothesis of no differential topology and a common trajectory is therefore fitted (d.). However, there is differential progression between conditions: the pseudotime distributions along the trajectory are not identical (e.) between conditions and we reject the null using the progressionTest.

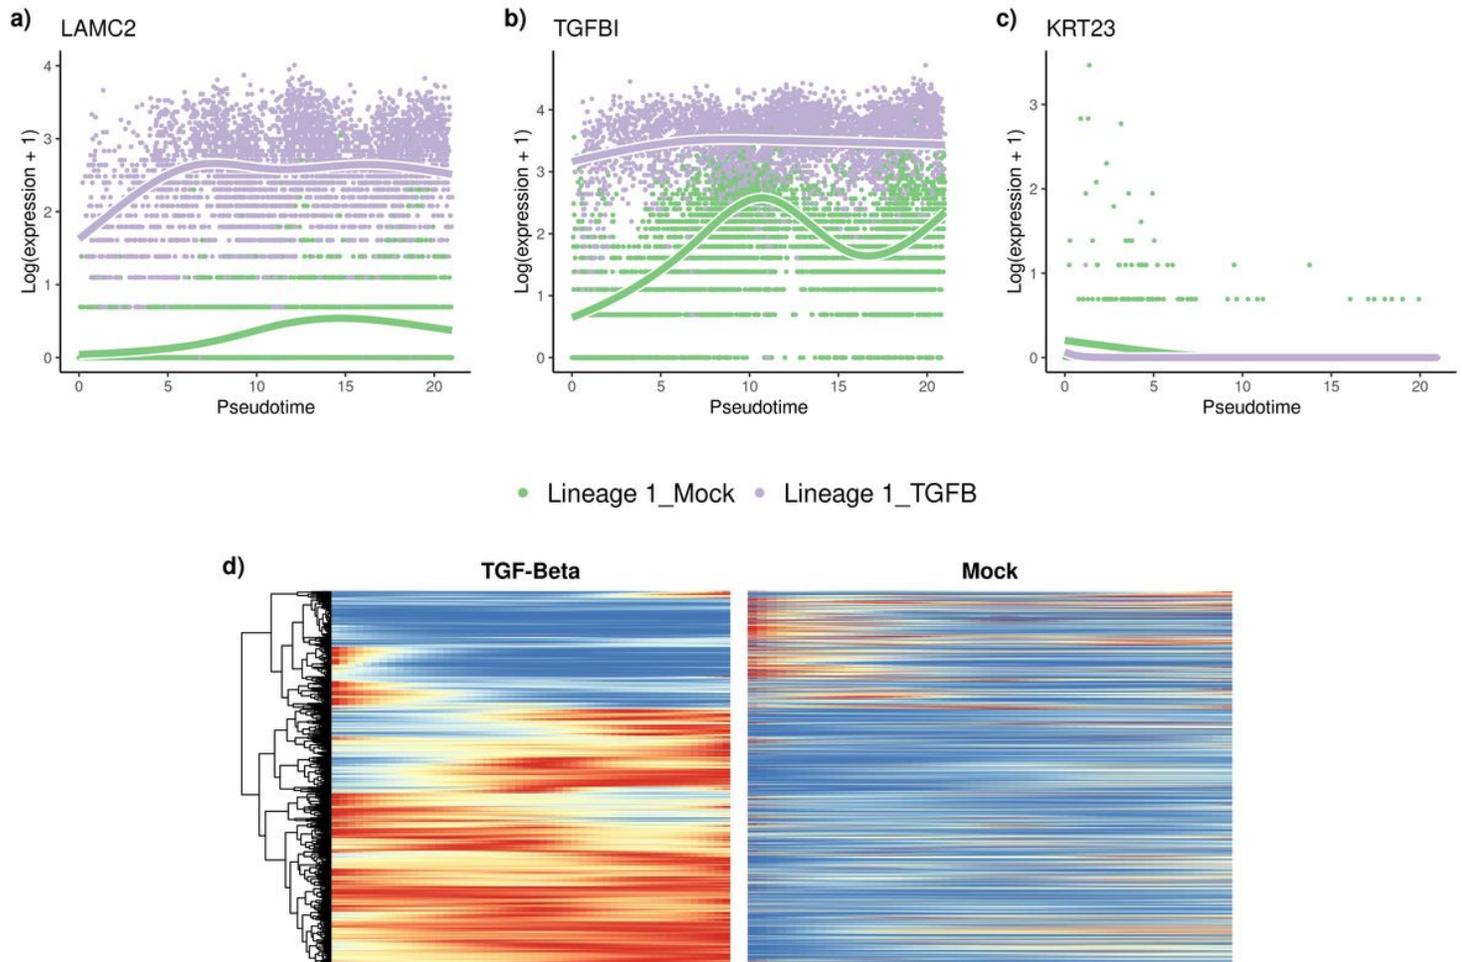

Figure 4

TGFB dataset: Differential expression. The tradeSeq gene expression model is fitted using the trajectory inferred by slingshot. Differential expression between conditions is assessed using the conditionTest and genes are ranked according to the test statistics. The genes with the highest (a.), second highest (b.), and smallest (c.) test statistics are displayed. After adjusting the p-values to control the FDR at a nominal level of 5%, we display genes for both conditions using a pseudocolor image (d.) after scaling each gene to a [0; 1] range.

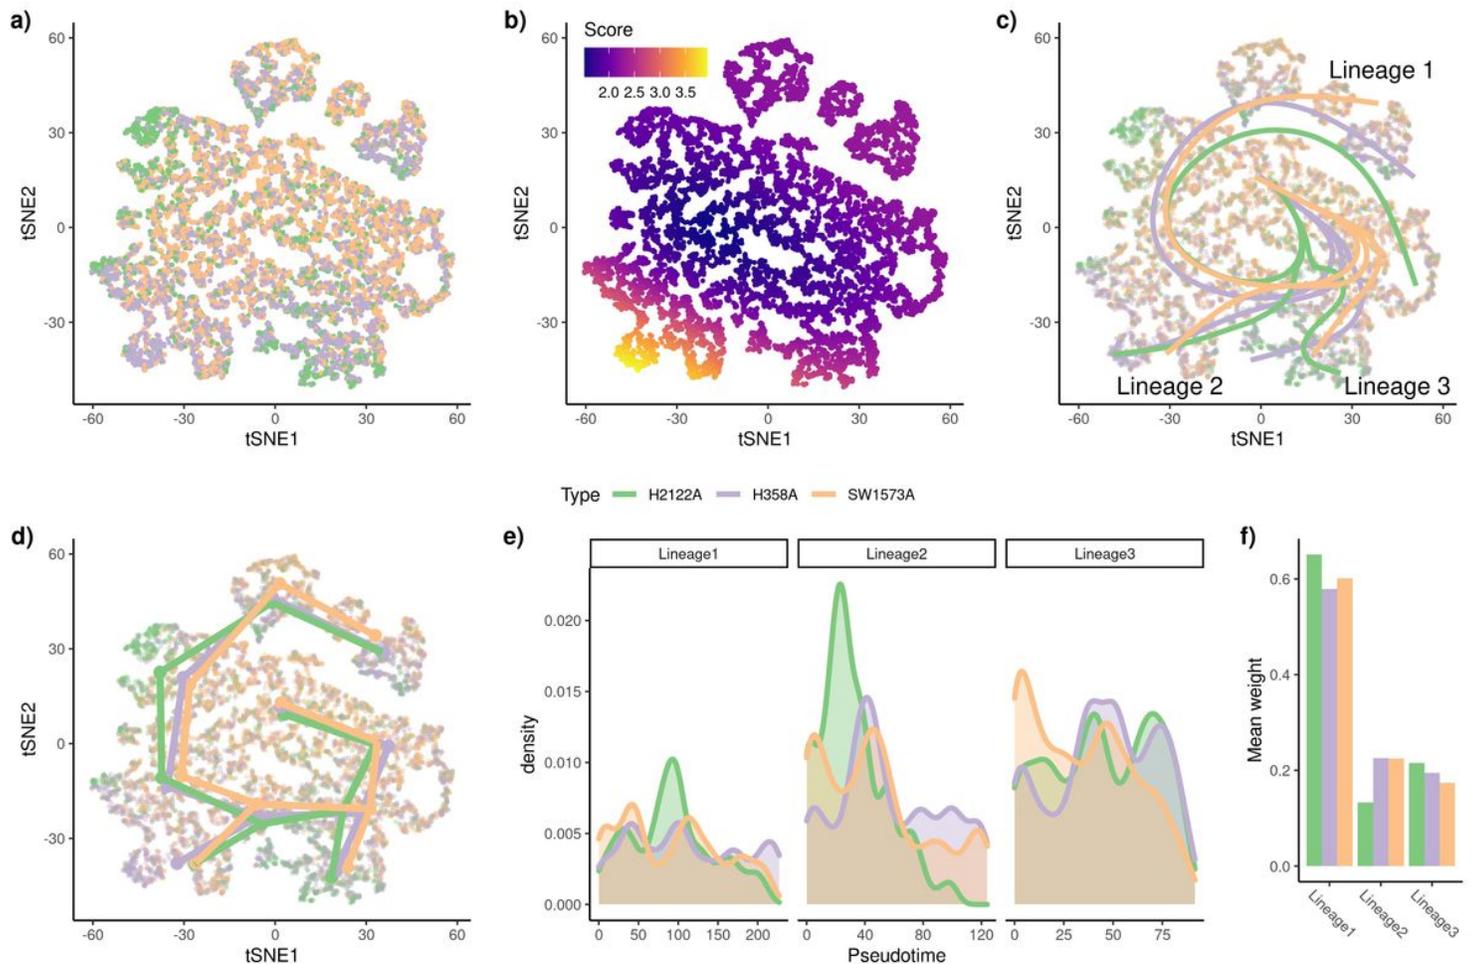

Figure 5

KRAS dataset: Differential topology, differential progression, and differential differentiation. Using the reduced-dimensional representation of the original publication (t-SNE), the cells can be colored by cancer type (a.). Using the cancer type label and the reduced-dimensional coordinates, an imbalance score is computed and displayed (b.). The topologyTest rejects the null hypothesis of a common trajectory, we thus fit one trajectory per condition (c.). However, the skeleton graphs have the same structure (d.), so we can progress to the next steps in the condiments work ow. There is differential progression (d.) and we indeed reject the null of identical pseudotime distributions along the trajectory using the progressionTest. Similarly, there is differential differentiation (e.) and we reject the null of identical weight distributions along the trajectory using the differentiationTest. Here, we summarize the distributions by looking at the average weight for each lineage in each condition, which already shows some clear differences.
