Abstract

Background: The goal of this study is to demonstrate the feasibility of [18F]fluorodeoxyglucose (FDG) positron emission tomography (PET)/magnetic resonance imaging (MRI) for non-invasive visualization of muscular, neurovascular, and skin changes secondary to complex regional pain syndrome (CRPS).

Methods: Seven adult patients with CRPS in the lower extremity and seven healthy adult controls participated in our [18F]FDG PET/MRI study. All participants received whole-body PET/MRI scans one hour after the injection of 10mCi [18F]FDG. Resulting PET/MRI images were reviewed by two radiologists. Metabolic and anatomic abnormalities identified, were grouped into muscular, neurovascular, and skin lesions. The [18F]FDG uptake of each lesion was compared with that of corresponding areas in controls using a Mann-Whitney U-test.

Results: On PET images, muscular, neurovascular, and skin abnormalities were found in 5, 4 and 2 patients, respectively. However, on MRI images, no muscular abnormalities were detected. Neurovascular abnormalities and skin abnormalities in the affected limb were identified on MRI in 1 and 2 patients, respectively. The difference in [18F]FDG uptake between the patients and the controls was significant in muscle ($p = 0.018$) and neurovascular bundle ($p = 0.0005$).

Conclusions: The increased uptake of [18F]FDG in the symptomatic areas likely reflects the increased metabolism due to the inflammatory response causing pain. Therefore, our approach combining metabolic ([18F]FDG PET) and anatomic (MRI) imaging may offer non-invasive monitoring of the distribution and progression of inflammatory changes associated with CRPS.

Introduction

Complex regional pain syndrome (CRPS) is a severe pain condition of extremities, presenting a variety of symptoms that significantly exceeds the expected clinical progression of the injury[1]. Depending on the type of the inciting injury, it is classified into two types: CRPS I if its onset has no association with a nerve injury, and CRPS II if it is caused by a confirmed nerve injury. Due to the complexity of symptoms and disease progression, it has been very challenging to identify the exact source of pain and design effective treatments for patients with CRPS[2].

A few diagnostic approaches have been adopted to aid the diagnosis of CRPS. Plain film X-ray and three phase bone scan (TPBS) have been used for identifying bone loss or resorption by CRPS. However, these changes may appear temporarily and only at specific stages of CRPS[3, 4]. Magnetic resonance imaging (MRI) facilitated examining pathologic changes in musculoskeletal tissues[5], but its effectiveness has not been fully established yet[3]. Therefore, there is a pressing clinical need for improved localization of

the CRPS-induced changes to better understand the disease mechanism and help monitor treatment effects.

In this communication, we introduce a novel imaging approach focusing on the detection of the inflammatory changes due to CRPS. Inflammation without infection is one of the key features of CRPS recognized more than 100 years ago[6]. Positron emission tomography (PET) imaging with [18F]fluorodeoxyglucose (FDG) has been frequently utilized for non-invasive localization of inflamed tissues in many disease indications. The simultaneous acquisition of high-resolution MRI can facilitate the accurate specification of lesions presenting abnormally high tracer uptake on PET[7]. We performed a [18F]FDG PET/MRI comparison study on CRPS patients and healthy controls to evaluate its feasibility for non-invasive detection of CRPS-induced changes.

Methods

Patient population

Seven patients diagnosed with CRPS in the lower extremity by confirming their symptoms and signs to the Budapest criteria[8] were enrolled in our study, and their initial evaluation results are summarized in Table 1. All patients were female, and the mean $\pm$ standard deviation / range of their age was 38.7 ± 12.4 y / 20-54y. Seven healthy controls were recruited to compare the [18F]FDG uptake (4 males and 3 females; age mean $\pm$ standard deviation, 30.0 ± 4.1 y; age range, 22-37y).

[18F]FDG PET/MR imaging

The blood glucose level of subjects was maintained under 180 mg/DL by fasting for at least four hours prior to the imaging session. A single 10mCi dose of [18F]FDG was administered intravenously to the subject one hour before imaging. All scans were conducted in a GE PET/MRI scanner (SIGNA PET/MR, General Electric Healthcare, Waukesha, WI, USA). Simultaneous PET and MRI scans covering the whole body in 8 to 10 stations were performed depending on the height of the patient.

Image review

A radiologic review of [18F]FDG PET and MRI images were performed by two board-certified radiologists. The [18F]FDG PET image review aimed to detect lesions of focally increased high uptake in the affected extremities in comparison with corresponding areas of healthy controls. MRI images were reviewed to identify lesions presenting either abnormally increased signal on the T2-weighted contrast or showing abnormal structural changes.

Statistical analysis

Abnormalities detected on PET and MRI were classified into three tissue categories: muscle, neurovascular bundle, and skin/subcutaneous tissue. For each lesion on the PET images, an ROI was manually drawn to measure the maximum standardized uptake value (SUV_{max}). For each tissue type, the

SUV_{max} of the lesions was compared with the SUV_{max} of healthy controls using the two-tailed Mann-Whitney U-test. The p-value of 0.05 was adopted as a significance level. The mean and the standard deviation of SUV_{max} of the patients and the healthy controls was also calculated for individual tissue groups.

Results

PET/MRI image review

Abnormalities were found at the reported site of pain in all seven patients on [18F]FDG PET, but in only three patients on MRI (Table 2). Increased uptake on foot muscles was the most frequent finding on PET (five patients), while, on MRI, skin thickening and nerve abnormalities were the most frequent observation (two patients, respectively). Figure 1 shows focally increased [18F]FDG uptake on the left extensor digitorum brevis muscle (1A, 1B) from a patient with left dorsal foot pain and on the left flexor digitorum brevis muscle (1C, 1D) from a patient with left plantar foot pain. Locally and globally increased [18F]FDG uptake on neurovascular bundles are respectively presented in Figure 2. The right tibial neurovascular bundle through the scar tissue at the ankle showed high [18F]FDG uptake from a patient with right foot pain (2A, 2B). The high [18F]FDG uptake was found bilaterally on the multiple neurovascular bundles including femoral, popliteal, and tibial neurovascular bundles from a patient with bilateral foot and leg pain (2C). Figure 3 displays a case of skin and subcutaneous tissue abnormalities on both [18F]FDG PET and MRI from a patient with right foot and lower leg pain.

[18F]FDG uptake comparison

Detected lesions of CRPS patients showed significantly higher [18F]FDG uptake than the corresponding regions in healthy controls (Figure 4). The mean $\pm$ standard deviation of SUV_{max} between the detected lesions from CRPS patients and corresponding tissues from healthy controls were 1.29 $\pm$ 0.29 vs 0.86 $\pm$ 0.19 (muscle), 1.38 $\pm$ 0.57 vs 0.73 $\pm$ 0.10 (neurovascular bundle), and 3.10 $\pm$ 2.97 vs 0.44 $\pm$ 0.08 (skin/subcutaneous tissues). The p-values from the SUV_{max} comparison in muscular and neurovascular tissues were 0.018 and 0.0005, respectively, indicating a significant difference between patients and healthy controls. The p-value for the skin/subcutaneous tissue comparison could not be computed due to a limited sample size.

Discussion

In this study, we evaluated the feasibility of [18F]FDG PET/MRI to detect metabolic and anatomic changes associated with CRPS. Radiologic evaluation and quantitative comparison confirmed that all seven patients with lower extremity CRPS exhibited significantly increased metabolism on [18F]FDG PET, possibly from inflammatory processes in CRPS. However, no single common abnormality was found in the affected limbs across all patients, reflecting the complicated heterogeneity of CRPS pathology.

Gross morphologic changes or signal abnormalities were identified at the site of elevated [18F]FDG uptake on MRI, but only from three patients (Patients 5,6, and 7). This suggests metabolic interrogation with [18F]FDG PET may identify CRPS-induced changes by earlier than MRI, and therefore potentially promote early and effective management of CRPS[9]. Note that the specification of lesions with high [18F]FDG uptake was only enabled by structural MRI data. For example, the subcutaneous tissue uptake in Figure 3 would probably have been misclassified into the muscle uptake if judged only by its location on PET images.

Our imaging findings may facilitate specific subtyping or staging of CRPS. All abnormal PET uptake was locally confined except the case of the patient 3 presenting the global uptake on multiple neurovascular bundles (Figure 2C). This likely supports the reported heterogeneity in the disease mechanism of CRPS[10], which could impart differing management approaches. High [18F]FDG uptake on the edematous skin and subcutaneous tissue (Figure 3) is another feature that could be unique to a specific subtype or stage of CRPS. Edema is supposedly composed of body fluid, lacking the cellular components for increased metabolism. However, our case of edema with elevated [18F]FDG uptake indicates the possibility to identify an inflammatory subtype of CRPS. It should be also noted that three cases of CRPS type I showed abnormal [18F]FDG uptake on peripheral nerves, while the only case of CRPS type II presented both PET and MRI abnormalities at the suspected nerve. This suggests that our method may provide the increased sensitivity to the causative nerve damage for the improved distinction between CRPS type I and II.

Our study has a few limitations, firstly, the relatively small number of enrolled patients and healthy controls. Our validation of the detected abnormalities regarding their potential contribution to pain is supported by their location, radiologic review and statistical comparison. However, a more direct evaluation of their association with pain, such as the outcome assessment of local anesthetic injection to detected abnormalities, would be desirable. There may be a chance that factors other than inflammation, such as increased muscle recruitment from limping, could result in increased muscular uptake of [18F]FDG in the favored limb. Therefore, additional diagnostic information, potentially through developments of novel MRI techniques in our case, might be necessary to improve the specificity.

In conclusion, we present a novel [18F]FDG PET/MRI approach that identified metabolic and structural abnormalities in muscles, neurovascular bundles, and skin likely due to the inflammatory process of CRPS. Our preliminary results demonstrate the diagnostic potential of this approach for the non-invasive monitoring of distribution and progression of CRPS-induced changes.

SUV_{max}: maximum standardized uptake value

Declarations

Ethics approval and consent to participate.

This study was approved by the institutional review board of Stanford university. All research data such as participant information and images were acquired in compliance with the Health Insurance Portability and Accountability Act. Informed consent was obtained from all individual participants included in the study.

Consent for publication

All individual participants signed informed consent regarding publishing their data and acquired images.

Availability of data and material

The datasets generated during and/or analyzed during the current study are not publicly available due to the fact we are 1) describing the off-label use of [18F]fluorodeoxyglucose and 2) the data is currently being utilized/analyzed for development of intellectual property, but are available from the corresponding author on reasonable request.

Competing interests

The authors, Daehyun Yoon, Peter Cipriano, and Sandip Biswal, received research support from General Electric Healthcare. No other potential conflicts of interest relevant to this article exist.

Funding

This study was in funded by NIH P41 EB015891 and General Electric Healthcare.

Tables

Table 1. Initial evaluation results of the recruited CRPS patients

Patient number	Pain location	Duration	CRPS Type
1	Right foot/leg	7 years	I
2	Left foot/ankle	5 years	I
3	Bilateral foot/leg	5 years	I
4	Right foot	4 years	I
5	Right foot/leg	2 years	I
6	Left foot/leg	2 years	II
7	Left foot	7 years	I

Table 2. Identified [18F]FDG PET and MRI abnormalities of foot muscles, neurovascular bundles, and skin from 7 CRPS patient participants.

Patient number	Modality	Muscle	Neurovascular bundle	Skin
1	PET	High FDG uptake on right dorsal foot muscles	None	None
	MRI	None	None	None
2	PET	High FDG uptake on left plantar foot muscles	None	None
	MRI	None	None	None
3	PET	High FDG uptake on left plantar foot muscles	High FDG uptake on bilateral plantar, tibial, femoral, popliteal nerves	None
	MRI	None	None	None
4	PET	High FDG uptake on right ankle scar, muscles	High FDG uptake on right posterior tibial nerve	None
	MRI	None	None	None
5	PET	None	None	High FDG uptake on subcutaneous / skin tissue from the right distal thigh to the foot
	MRI	None	None	Skin thickening and subcutaneous edema throughout the right leg
6	PET	None	High FDG uptake on left saphenous nerve	High FDG uptake on subcutaneous tissue around left medial and lateral malleoli
	MRI	None	Enlarged left saphenous nerve	Subcutaneous tissue thickening around left medial and lateral malleoli
7	PET	High FDG uptake on left dorsal foot muscles	High FDG uptake on the left saphenous nerve	None
	MRI	None	Increased signal on the left saphenous, sural nerves	None

Figures

Figure 1

Locally high [18F]FDG uptake on foot muscles at the site of pain symptom. High [18F]FDG uptake was identified (red arrows) on the left extensor digitorum brevis muscle (A: PET only, B: PET/MRI co-registered) from patient 7 and left flexor digitorum brevis muscle (C: PET only, D: PET/MRI co-registered) from patient 2. The unit of PET signal on the images is SUV. No structural damage or abnormal signal intensity was observed on the MRI image.

Figure 2

Increased [18F]FDG uptake on neurovascular bundles at the site of pain symptom. Locally increased [18F]FDG uptake was detected on the tibial neurovascular bundle passing through the scar tissue at the ankle of patient 4 and marked by the yellow arrow (A: PET only, B: PET/MRI co-registered). Globally high [18F]FDG uptake on multiple neurovascular bundles from patient 3 with bilateral foot and leg pain (C: PET only, white arrows). The unit of PET signal on the images is SUV.

Figure 3

[18F]FDG PET and MRI abnormalities of skin and subcutaneous tissue of the symptomatic lower leg from patient 5 (A: PET only, B: PET/MRI co-registered). Increased uptake of [18F]FDG was identified on PET (white arrows) where edematous skin and subcutaneous tissue thickening was detected on MRI. The unit of PET signal on the images is SUV.

Figure 4

Mean and standard deviation of [18F]FDG SUVmax in muscle, neurovascular bundle, and skin lesions of CRPS patients and corresponding tissues of healthy controls. SUVmax in the lesions in muscle and nerve tissues show statistically significant difference than controls ($p < 0.05$).
