Abstract

Objectives

To summarise the surgical outcomes in patients with cardiogenic shock supported by preoperative extracorporeal membrane oxygenation (ECMO).

Methods

Between May 2012 and August 2017, eight patients with cardiogenic shock patients supported by ECMO underwent emergency surgery; four of them had isolated coronary artery bypass grafting, three had coronary artery bypass grafting with mitral replacement, and one had mitral valve replacement with left ventricular posterior wall repair.

Results

All eight patients successfully weaned off from ECMO after their surgeries. Postoperative ECOM time ranged from 6.8 to 228 hours, with a median of 68.4 hours. Two patients died postoperatively while another six survived. The follow up time for the six patients was ranged from three to 66 months whereby one of them died in the third month due to septicaemia. The remaining five patients survived with good cardiac function based on the NYHA classification.

Conclusion

ECMO is a vital bridge in the preparation of critically-ill patients for cardiac surgery. It is associated with acceptable outcomes among the majority of the patients.

Introduction

Extracorporeal Membrane Oxygenation (ECMO) was first applied clinically in 1973 [1–2]. Currently, ECMO is mainly used as circulatory assistance to rescue patients with acute circulatory and/or respiratory failure. Its two main purposes are to serve as a bridge-to-recovery (BTR) in patients who are suffering from heart failure and secondly, as a bridge-to-next decision (BTD) where it serves as a temporary intervention until further clinical decisions can be made. The examples of BTD include surgery, interventional treatment, long-term ventricular assist device implantation, heart transplantation [3], etc. To date, there are limited published studies on the surgical outcomes of cardiogenic shock patients supported by ECMO. We aimed to contribute to the literature by reporting on the ECMO cases in the Cardiac Surgery Department of Beijing Anzhen Hospital and to evaluate the surgical efficacy of ECMO on cardiac patients.

Materials And Methods

This study was conducted from May 2012 to August 2017. All the patients with cardiogenic shock who received ECMO before emergency surgery were included.

Patients would be considered for ECMO support if they have the following clinical signs: systolic blood pressure < 90 mm Hg, required two or more high-dose vasopressors, intra-aortic balloon pump counterpulsation (IABP) needed to maintain blood pressure at 90 mm Hg, peripheral vascular constriction, cold extremities, irritability, altered mental state, urine output < 30 ml/h. High-dose vasopressor included dopamine $\geq 10 \mu\text{g/kg/min}$, adrenaline $\geq 0.05 \mu\text{g/kg/min}$, dobutamine $\geq 1 \mu\text{g/kg/min}$, or milrinone $\geq 0.5 \mu\text{g/kg/min}$.

Preoperatively, all eight patients were put on ECMO using Maquet (2050 package) or Medtronic pump head, as well as the Medos membrane lung combination. The MO loop was prefilled with lactated Ringer's solution or normal saline. The pulse-arterial ECMO (VA-ECMO) mode provided circulatory assistance through the femoral arteriovenous catheters. The intubation were all made of Medtronic Carmeda coating (19 Fr or 21 Fr for vein, 15 Fr or 17 Fr for artery). Among these patients, two received percutaneous puncture catheterisation and six underwent incision catheterisation with the placement of distal irrigation. The ECMO operation was performed in the catheterisation lab for three of the patients, and in the EICU for another four patients. One patient underwent the procedure in the normal ward. During ECMO, close monitoring was conducted every four hours to maintain the activated coagulation time (ACT) at 180–220 s and the activated partial thromboplastin time (APTT) at 50–60s. Appropriate sedatives such as fentanyl, propofol, and dexmedetomidine were added to the intravenous pumps. The patients' conditions were closely monitored for any signs of recovery. All of the eight patients were supported with ECMO and mechanical ventilation. A protective lung ventilation strategy was adopted. Ventilator parameters were adjusted based on the blood gas results. When the patients showed good lung functions, sedation would be stopped and patients would be extubated. However, one of them awakened and had to proceed with ECMO without sedation. Bedside echocardiography was performed daily to assess the patients' cardiac function. If patients became haemodynamically stable, we would attempt to stop the ECMO for one hour. If the patients continued to be stable with good blood circulation and cardiac function, the ECMO would be removed.

All eight patients underwent median sternotomy under general anaesthesia. Four patients underwent off-pump coronary artery bypass grafting while on ECMO with an intraoperative ACT of > 380 s. The other four patients underwent on-pump coronary artery bypass grafting and they were heparinised to achieve ACT > 480 s. Conventional ascending aorta cannulation, as well as superior and inferior vena cava cannulation, were established. The ECMO cannula was disconnected from the loop. Following that, the loop would be attached to a connector to turn it into a closed-loop self-circulation. The aortic cross-clamp was applied before starting the cardioplegia solution by cooling the heart surface with ice debris.

Surgically, three patients underwent coronary artery bypass surgery and mitral valve replacement. Another patient underwent routine mitral valve replacement with left ventricular posterior wall repair. In the

operation, a sidewall clamp was first applied on the aorta while proximal stapler was used to anastomose the proximal end of the target vessel before being moved down to perform a distal anastomosis. The other four patients underwent simple coronary artery bypass grafting. All the bridging vessels used were the great saphenous veins. Of the total 15 grafts, five were for the anterior descending branch, one was for the diagonal branch, six for the circumflex branches, and three for the posterior descending branches. Mitral valve replacement was performed in four patients in which the posterior leaflet was retained and the intermittent suture was implanted. An artificial mechanical valve was used (Medtronic AP360 M24 or 26) for the patient with a ruptured posterior wall of the left ventricle as a result of visceral trauma. The valve was repaired with the intracardiac interrupted suture combined with the epicardial “sandwich” suture. All the patients were followed-up on November 30th 2017, via phone and by outpatient visits to determine their survivals and cardiac functions.

Results

There were six males and two females with an age range between 15 and 78 years old (55.5 ± 15.5) and a weight range between 60 and 100kg. The preoperative ejection fraction was between 28 and 70% (52.0 ± 14.0), the left ventricular end-diastolic diameter ranged between 43 and 65 (54 ± 7) mm, and the left ventricular end-systolic diameter was between 43 and 65 (35 ± 7) mm. Among them, six patients had an acute myocardial infarction, one patient had unstable angina, while another suffered from cardiac trauma. Three of them received cardiopulmonary resuscitation (Table 1).

The preoperative ECMO time ranged from 0.5 to 72.5 (24.2 ± 29.8) hours. The mean surgical time was 254.4 ± 56.6 min and the extracorporeal circulation time and the aortic block time were slightly lower at 139.3 ± 34.0 min and 92.5 ± 24.1 min respectively. Perioperative blood investigation showed red blood cells 6–46 U (median 11.5 U), plasma 400–2800 ml (median 900 ml), platelets 0–10 U (median 2.5 U). Lastly, the postoperative-ventilator assistance time ranged from 37 to 546 hours, with a median of 162 hours.

All eight patients were successfully weaned off ECMO and ventilation. However, only six patients survived and were discharged, thus giving a survival rate of 75%. Postoperative ECMO assistance time ranged from 6.8 to 228 hours with a median of 68.4 hours. There were two deaths (25.0%) during the perioperative period, one of them died of septicaemia and multiple organ failure while another died of a stroke and multiple organ function. In addition, five patients (62.5%) experienced renal failure after the operation and required dialysis. Two patients suffered from lung infections (25.0%) and upper gastrointestinal bleeding (25.0%) respectively. Type I respiratory failure occurred in one patient (12.5%) and acute liver failure also occurred in one patient (12.5%). All six cases were followed up after the operation and the follow up time ranged from 3 to 66 months with a mean of 12.5 months. However, one patient died of a blood infection three and a half months after the operation. The remaining five patients showed good cardiac functions with grade I NYHA classification (Table 2).

Discussion

A significant reduction in cardiac output can cause severe acute circulatory failure that is associated with a high mortality rate. The rate of hospitalised death due to cardiogenic shock can be as high as 80%. Thus, it is important to reverse cardiogenic shock. In this study, emergency ECMO was used to assist the surgical treatment of cardiogenic shock. The subsequent in-hospital mortality rate was only 25.0%. Although ECMO is generally used for cardiogenic shock after cardiac surgery [4], a recent study by Bastan et al. [5] recruited 517 patients who received ECMO as a result of postoperative cardiogenic shock. The ECMO removal rate was 63% and the survival rate was 24.8%. The 6- and 12-month follow up survival rates were 17.6% and 16.5% respectively while the 5-year survival rate was 13.7%. According to the study, the risk factors for in-hospital death included old age, preoperative renal insufficiency, diabetes, obesity, intraoperative lactic acidosis, and high scores of the European Heart Surgery Risk Assessment System (EuroScore).

In this study, the patients with cardiogenic shock received ECMO before surgery. The ECMO removal rate was 100% and the survival rate at discharge was 75%. Thus, in comparison, preoperative implantation of ECMO is likely to confer a better prognosis than ECMO implantation after cardiac surgery. In a 2009 study by Bautista-Hernandez et al. [6], the surgical mortality was 38% among 26 patients who received a preoperative application of ECMO for congenital heart disease. Some of the complications of ECMO included death, inability to remove ECMO, and long-term dependence on ECMO. Another study in Taiwan reported a 50% death rate among 16 cases of CABG patients who received ECMO reports [7]. Higher mortality was observed among those over 60 years old and those with severe hypoxic encephalopathy.

There are several limitations to this study. This was a retrospective study with a small number of cases.

Conclusion

In short, preoperative ECMO support in patients with cardiogenic shock provide critically-ill patients with opportunities for surgical treatment. It is also associated with better surgical outcomes.
