**Abstract**

Background: COVID-19 led to significant morbidity and mortality. To investigate contributing factors to severity and examine whether Azvudine can reduce mortality, we conducted a single-center, retrospective cohort study.

Method: 4201 COVID-19 patients discharged from our hospital were enrolled. Logistic regression analysis and ROC curve were used to investigate the role of comorbidities, laboratory parameters and clinical manifestation on progression of COVID-19. Propensity-score models conditional on baseline characteristics and Univariate Cox regression model were used to examine whether Azvudine can reduce the mortality of COVID-19.

Result: Age, male sex, cerebrovascular disease, chronic kidney disease, liver disease, tumor and chronic lung disease were associated with elevated risk of mortality and chronic kidney disease contributed the most risk. Uric acid showed a U-shape risk of severity. Both hyperuricemia and hypouricemia increased the risk of severity. D-dimer, NT-BNP, LDH and FT3 were the most sensitive and specific markers for the prediction of mortality. Poor appetite, consciousness deterioration, polypnea and persistent high fever were associated with elevated risk of severity. Compared with no antiviral group, Azvudine can reduce the COVID-19 mortality (hazard ratio 0.708(95% confidence interval 0.516 to 0.971), P=0.032). There was no significant difference in mortality reduction between Molnupiravir and Azvudine(P=0.486).

Conclusions: Among COVID-19 patients, age, male sex and comorbidities can affect progression of COVID-19. D-dimer, NT-BNP, LDH, FT3, UA, poor appetite, consciousness deterioration, polypnea and persistent high fever can help doctors predict severe illness. Azvudine is neck and neck with Molnupiravir in the mortality reduction among COVID-19.

## 102 **Introduction**

103 The novel coronavirus disease (COVID-19) is a highly contagious disease  
104 caused by the SARS-CoV-2 virus, leading to significant morbidity and  
105 mortality. Until fall 2022, China maintained strict 'zero-COVID' policy.  
106 Starting from Dec. 7, nearly all interventions of 'zero-COVID' policy were  
107 removed given the high transmissibility of the Omicron variants BA.5 and  
108 BF.7 present in China. By the end of May 2023, it had caused two waves.

109 Here, we conducted a single-center, retrospective cohort study during  
110 the outbreak caused by Omicron. Comparing the peaks of these two waves,  
111 we inferred that the population of COVID-19 survivors had immune protection  
112 against Omicron and high titer level of antibodies may be maintained for  
113 about 3-4 months (Fig 1). Accurately analyzing the clinical features of  
114 hospitalized patients is valuable strategies to handle large infection waves  
115 caused by Omicron variant.

116 RNA replicase, as the core component of viral transcription and replication,  
117 is highly conserved in viral variant species, and antiviral agents developed  
118 for this target are not susceptible to viral mutation. At present, RNA  
119 polymerase (RdRp) inhibitors recommended by Chinese guidelines include  
120 Molnupiravir and Azvudine. Molnupiravir use within five days of testing  
121 positive for SARS-CoV-2 has been shown to reduce the risk of mortality[1].  
122 Several studies demonstrated that Azvudine could reduce the duration of  
123 virus clearance in COVID-19 patients[2]. Therefore, concerns arise about the  
124 clinical effectiveness of Azvudine versus Molnupiravir in COVID-19 patients.

## 126 **Methods**

127 Setting : Data were collected from The Fifth Affiliated Hospital of Sun Yat-sen  
128 University. Since the COVID-19 epidemic in 2019, the hospital had been the

129 only designated hospital in Zhuhai city under the "zero COVID-19" policy,  
130 and had rich experience in the treatment of severe COVID-19 patients. The  
131 study was conducted according to the guidelines of the Declaration of  
132 Helsinki and approved by the Institutional Ethics Committee of the Fifth  
133 Affiliated Hospital of Sun Yat-sen University ([2023]K200-1). The study was  
134 registered on ClinicalTrials.gov. (NCT06006611). The informed consents  
135 from patients were not required.

136 Data sources : We extracted data from November 1, 2022 to May 31, 2023.

137 Data domains used were inpatient diagnoses, inpatient pharmacy records,  
138 electronic case record and laboratory test results.

139 Cohort : Overall, 4201 patients were enrolled to study the role of clinical  
140 manifestation and underlying comorbidities on progression to severe  
141 COVID-19 case. The criteria of severe cases were based on the resting  
142 state, oxygen saturation  $\leq 93\%$  during air inhalation,  $(PaO_2)/(FiO_2)$   
143  $\leq 300\text{mmHg}$ , pulmonary imaging showing significant progress of  $> 50\%$   
144 within 24-48 hours, respiratory failure requiring mechanical ventilation,  
145 shock and other organ failure needing intensive care unit treatment. We  
146 conducted binary logistic regression analysis for the relative risk of  
147 comorbidities and clinical manifestation on progression of COVID-19 patients.  
148 Model likelihood ratio test was used to estimate whether the model is valid.  
149 Hosmer-Lemeshow test was used to estimate goodness of fit. ROC curve  
150 analysis was used to explore sensitivity and specificity of laboratory  
151 parameters for the prediction of mortality among COVID-19 patients.

152 In order to observe whether Azvudine can reduce the mortality of  
153 COVID-19 patients, patients with these conditions were excluded: 1) younger  
154 than 18 years; 2) received other antiviral agents; 3) received both Azvudine  
155 and Molnupiravir. Then 3945 participants were enrolled. First, patients were  
156 divided into Azvudine group and no antiviral group. The endpoint was  
157 all-cause death. Patients were observed from the date of admission until  
158 discharge or death, whichever came first. We used propensity-score models  
159 conditional on baseline characteristics, and the probability of receiving  
160 Azvudine was estimated in an approach of caliper matching without  
161 replacement, with a caliper width of 0.2. The baseline characteristics  
162 included age, sex, systemic steroid, mechanical ventilation and severity. The  
163 standard mean differences (SMDs) were used to assess the balance of each  
164 baseline characteristics between groups before and after propensity-score  
165 matching which less than 0.1 indicating covariate was balanced (Table2,3).

166 Univariate Cox regression model was used to estimate a hazard ratio (HR)  
167 with 95% confidence interval (CI) for the result between these two groups.  
168 Second, patients were divided into Azvudine group and Monotamivir group  
169 by the same method. All statistical analyses were conducted with SPSS  
170 version 22. P value less than 0.05 was statistically significant.

171

## 172 **Result**

### 173 **Comorbidities**

174 Compared with survival COVID-19, age was associated with elevated risk  
175 of progression to death (relative risk 1.042(95% confidence interval 1.031  
176 to1.053); cerebrovascular disease (relative risk 1.362 (95% confidence  
177 interval 0.999 to1.856); chronic kidney disease (relative risk 4.083 (95%  
178 confidence interval 3.031 to 5.499); liver disease (relative risk 1.956 (95%  
179 confidence interval 1.363 to 2.806) ; tumor (relative risk 1.799 (95%  
180 confidence interval 1.303 to 2.484) and chronic lung disease (relative risk  
181 1.320(95% confidence interval 0.929 to 1.876). Female had a lower risk of  
182 progression to death (relative risk 0.908 (95% confidence interval 0.676 to  
183 1.218) (Fig 2). Furthermore, ROC curve analysis was used to explore  
184 sensitivity and specificity of age for the prediction of mortality among  
185 COVID-19 patients. The cutoff value of age was 66.5, sensitivity 0.721 and  
186 specificity 0.583(Fig 3).

187

### 188 **Laboratory parameters**

189 Accurate and rapid laboratory diagnosis of COVID-19 infection and its  
190 deterioration is one of the milestones of pandemic control. Comparing the  
191 diagnostic and prognostic accuracy of mainly used laboratory parameters  
192 (eosinophils, lymphocyte, uric acid (UA), aspartate transaminase (AST),  
193 D-dimer, creatine kinase (CK), NT-brain natriuretic peptide (NT-BNP),  
194 squamous cell carcinoma antigen (SCC), lactate dehydrogenase (LDH) and  
195 free triiodothyronine (FT3) of COVID-19 patients can assess the most  
196 appropriate biomarker used in severe patients. Our results revealed that the  
197 level of AST, D-dimer, CK, NT-BNP, SCC, LDH were significantly increased,  
198 while eosinophils, lymphocyte and FT3 were significantly decreased among  
199 severe COVID-19 patients when compared with non-severe ones (Fig 4).  
200 Binary logistic regression analysis was used to evaluate the role of UA on  
201 progression to severe COVID-19. Compared with <180umol/L group,  
202 180-360µmol/L and 360-540µmol/L groups were associated with lower risk of  
203 severity (relative risk 0.551(95% confidence interval 0.414 to0.734), (relative

204 risk 0.807(95% confidence interval 0.599 to1.086). >540 $\mu$ mol/L group was  
205 associated with elevated risk of severity (relative risk 2.546(95% confidence  
206 interval 1.812 to3.577) (Fig 5). Furthermore, ROC curve analysis was used to  
207 explore sensitivity and specificity of laboratory data for the prediction of  
208 mortality among COVID-19 patients. Our results revealed that D-dimer ,  
209 NT-BNP, LDH and FT3 are the most sensitive and specific markers. Youden  
210 index was used to find cutoff value (Fig 6). The cutoff value of D-dimer was  
211 1.025 $\mu$ g/ml, sensitivity 0.800 and specificity 0.670; NT-BNP was  
212 449.500pg/ml, sensitivity 0.789 and specificity 0.680; LDH was 284.75U/L,  
213 sensitivity 0.648 and specificity 0.760; FT3 was 3.085  $\mu$ mol/L, sensitivity  
214 0.670 and specificity 0.735.

215

## 216 **Clinical manifestations**

217 The main clinical manifestations of COVID-19 patients include fever,  
218 cough, sore throat, rhinobyon, running nose, diarrhea, muscle soreness,  
219 conjunctivitis, hyposmia and hypogeusia. In addition, we had observed that  
220 some COVID-19 patients felt weak, poor appetite, altered state of  
221 consciousness, somnipathy, weight loss and other manifestations. We  
222 reviewed the inpatient records and 2,312 patients with above symptoms who  
223 were clearly caused by COVID-19 were investigated (table1). Binary logistic  
224 regression analysis was used to evaluate the role of clinical manifestations on  
225 progression to severe COVID-19. Compared with non-severe COVID-19,  
226 consciousness deterioration was associated with elevated risk of progression  
227 to severe illness (relative risk 4.802 (95% confidence interval 3.4792 to  
228 6.628); polypnea (relative risk 2.702 (95% confidence interval 2.158 to3.382);  
229 poor appetite (relative risk 1.536 (95% confidence interval 1.213 to 1.945);  
230 fever (relative risk 1.56 (95% confidence interval 1.208 to 2.013) and wek  
231 (relative risk 1.082 (95% confidence interval 0.848 to 1.380) (Fig 7).

232 We calculated the duration of fever from onset of COVID-19. 1287 cases  
233 recorded explicit fever duration. Binary logistic regression analysis was used  
234 to evaluate the role of fever duration on progression to severe COVID-19.  
235 Fever duration was associated with elevated risk of progression to severe  
236 illness (relative risk 1.07 (95% confidence interval 1.05 to 1.09) (Fig 8).

237

## 238 **Antiviral agent**

239 RNA polymerase (RdRp) inhibitors recommended by Chinese guidelines  
240 include Molnupiravir and Azvudine. Among 4201 hospitalized COVID-19

241 patients, 1112 Azvudine recipients, 111 Molnupiravir and 2722 no antiviral  
242 recipients were eligible for inclusion (Fig 9). Univariate Cox regression  
243 model was used to estimate whether Azvudine can reduce the mortality of  
244 COVID-19 illness. To assess the validity of the proportional hazard  
245 assumption, the assumption was assessed by log-minus-log-survival function  
246 and found to hold (Fig 10). Compared with no antiviral group, receiving  
247 Azvudine can reduce the mortality of COVID-19 illness (hazard ratio 0.708(95%  
248 confidence interval 0.516 to 0.971),  $P=0.032$ (Fig 11). Log-rank test was used  
249 to estimate the difference between Molnupiravir and Azvudine. There was no  
250 significant difference in mortality reduction between Molnupiravir and  
251 Azvudine( $P=0.486$ ) (Fig 12).

252

## 253 **Discussion**

254 Our study revealed that age, cerebrovascular disease, chronic kidney  
255 disease, liver disease, tumor and chronic lung disease were associated with  
256 elevated risk of COVID-19 mortality. Chronic kidney disease contributed the  
257 most risk. Adequate renal, liver and lung function are essential for host  
258 survival and adaptation to the rapidly changing internal environment. Age  
259 attribute to the decline in organ function and immunity[3]. Our result  
260 supported the idea that female was associated with reduced risk of COVID-19  
261 mortality. Autoimmune disease, hypertension and cardiovascular diseases  
262 also showed a weak association with lower COVID-19 mortality although it  
263 did not reach a statistical significance. It seemed to be what we not  
264 expected.

265 The possible reasons given in these studies are as follows: (1)  
266 Angiotensin converting enzyme 2 (ACE2) is the receptor for the attachment  
267 and entry of SARS-CoV-2 into the host cells[4]. Lupus and certain types of  
268 malignancies can promote ACE2 expression and activity[5].(2)Several clinical  
269 and experimental data indicated that methotrexate has certain protective  
270 effects on SARS-CoV-2 infection via down regulating ACE2[6]; Tumor  
271 necrosis factor inhibitor (anti-TNF) use was associated with a reduced odds  
272 of hospitalization in patients with rheumatic disease.(OR 0.40, 95% CI 0.19 to  
273 0.81)[7]; Hydroxychloroquine is known to increase the pH of endosomes,  
274 which inhibits membrane fusion, a required mechanism for viral entry into  
275 the cell[8]; For patients who have wild-type of ACE2 and TMPRSS2, a  
276 combination of camostat with hydroxychloroquine may have clinical  
277 benefit[9]; Although cytokine blockers and Janus kinases (Jak) inhibitors have  
278 raised theoretical concerns with regard to autoimmune disease therapy, it

279 should be noted that these agents are currently considered for clinical  
280 therapy of COVID-19 cases with hyperinflammation and ARDS[10]. These  
281 may help explain why autoimmune disease with underlying medicine showed  
282 a weak association with lower COVID-19 severity and mortality. (3) The  
283 administration of ACEI/ARB drugs had positive effect on reducing D-dimer  
284 and the number of people with fever[11]. ACEI/ARB therapy was not  
285 associated with increased risk of all-cause mortality or severe manifestations  
286 in patients with COVID-19[12]; Recent studies indicated that the use of  
287 statins lowered mortality by 42% in hospitalized patients with COVID-19 (HR  
288 = 0.58 with (0.43-0.8) 95% CI; p = 0.01). A[13] meta-analysis by Kow et al.  
289 including 8990 COVID-19 patients found statins reduce the risk of fatal or  
290 severe disease by 30%. These [13] results may be caused by the pleiotropic  
291 activity of statins, and recent studies suggested various mechanisms that  
292 may directly affect SARS-CoV-2 endocytosis (ACE2), replication (main  
293 protease and RNA polymerase) or indirect mechanisms unrelated to  
294 coronavirus infection, such as anti-inflammatory, anti-coagulant effects or  
295 endothelial function improvement[14]; Aspirin was associated with a small  
296 increase in the rate of being discharged alive within 28 days[15]. Therefore,  
297 we supported that autoimmune disease, hypertension and cardiovascular  
298 diseases themselves were associated with elevated risk of COVID-19 severity,  
299 but the underlying medicine could influence the risk. It required further  
300 study for us to clarify this issue.

301 Our findings provide evidence that markedly elevated D-dimer levels  
302 occurred in severe COVID-19 patients. FT3 serum levels are lower in patients  
303 with severe symptoms[16]. Whether thyroxine replacement therapy is  
304 beneficial to patients needs further research. Hyper-inflammation and  
305 cytokine storm may be linked to more severe disease. Neutrophilia,  
306 lymphopenia and high levels of LDH were common symptoms in severe  
307 COVID-19 disease[17]. Eosinophils release several cytokines involved in  
308 homeostasis maintenance and Th2-related inflammation. In the context of  
309 SARS-CoV-2 infection, emerging evidence indicates that eosinopenia seems  
310 to be an indicator of severity among patients with COVID-19, whereas an  
311 increased eosinophil count is associated with a better prognosis, including a  
312 lower incidence of severity and mortality[18]. SCC increased significantly in  
313 severe cases of COVID-19 as compared with mild cases. It was consistent  
314 with one study that severe SARS-CoV-2 infection may represent a marker of  
315 an undiagnosed lung cancer[19]. Low serum levels of uric acid are common  
316 and associate with disease severity and with progression to respiratory

317 failure requiring invasive mechanical ventilation. It might depend on  
318 antioxidant, endogenous modulator of innate immunity of uric acid which can  
319 inhibit the cytokine storm observed during COVID-19[20]. In our study, uric  
320 acid showed a U-shape risk on severity of COVID-19. The possible reasons  
321 are as follows: The evidences obtained by basic science suggest  
322 hyperuricemia can induce inflammation, endothelial dysfunction,  
323 proliferation of vascular smooth muscle cells, and activation of the  
324 renin-angiotensin system[21]. Therefore, we are inclined to support that both  
325 hyperuricemia and hypouricemia increase the risk of progression to severe  
326 COVID-19.

327 The clinical manifestation include cough, rhinobyon, sore throat,  
328 muscle soreness, dizziness, headache and somnipathy forebode upper  
329 respiratory tract infection (URTI). Diarrhea, nausea and vomiting forebode  
330 gastrointestinal symptoms. They are common symptoms in mild COVID-19.  
331 But, Poor appetite may result from edema of the mucosa of the digestive  
332 tract due to heart failure and it will make the body week and lack of energy  
333 to fight off viruses. Consciousness deteriorates forebode that the body is in a  
334 serious state of ischemia and hypoxia and the internal environment is  
335 disturbed. Polypnea forebodes failure of heart and lung function. In addition,  
336 with the extension of fever duration, the incidence of severe diseases will  
337 increase. We should pay more attention to these patients with poor appetite,  
338 consciousness deterioration, polypnea and persistent high fever.

339 Azvudine was recommended by Chinese health authorities for  
340 COVID-19 treatment. The mechanism is that Azvudine could be embedded  
341 during RNA synthesis of SARS-COV-2 and inhibits related polymerases,  
342 finally leading to RNA replication termination[2]. Azvudine is the most widely  
343 used antiviral against COVID-19 in China. After matching the baseline  
344 characteristics our study supported that Azvudine was effective in reducing  
345 the COVID-19 mortality compared with no antiviral group. Molnupiravir was  
346 recommended by Chinese health authorities for COVID-19 treatment as RNA  
347 polymerase inhibitors too. There is no significant difference between  
348 Azvudine and Molnupiravir in reducing COVID-19 mortality in our study.

349

## 350 **Conclusion**

351 Risk factors for severe COVID-19 include older age, male sex and  
352 pre-existing comorbidities .Underlying medicine may affect the risk. D-dimer,  
353 FT3, lymphopenia, LDH and SCC can help us predict COVID-19 severity. Uric  
354 acid showed a U-shape risk on COVID-19 severity. Poor appetite,

355 consciousness deterioration, polypnea and persistent high fever forebode  
356 severity. Azvudine was effective in reducing COVID-19 mortality and was not  
357 significantly different from Monotamivir.
