**Version of Record:** A version of this preprint was published at Nutrition Journal on October 3rd, 2021. See the published version at <https://doi.org/10.1186/s12937-021-00739-9>.

# Abstract

**Background:** A growing number of researches supported that dietary fructose was associated with all the key features of metabolic syndrome (MetS). However, there was no related epidemiological studies among Chinese population despite that cases of MetS increased sharply. This study explores the relationship between dietary fructose and MetS among Chinese residents aged 45 and above.

**Methods:** A total of 25528 participants (11574 males and 13954 females) were included in this nationwide representative cross-sectional study of China National Nutrition and Health Survey. Dietary fructose intake was assessed by 3-day 24-h dietary records. MetS was defined by the International Diabetes Federation and Chinese Diabetes Society criteria.

**Results:** The consumption of dietary fructose was 11.6g/day for urban residents and 7.6g/day for rural residents. Fruits and vegetables as well as their products were the main food sources. There was no association between dietary fructose intake and the risk of MetS in both urban ( $P = 0.315$ ) and rural residents ( $P = 0.230$ ) after adjustment for confounding factors. Moreover, for urban residents participating physical activities, the risk of MetS in the fourth quartiles (OR: 0.67; 95%CI: 0.52-0.86) was reduced compared with the first quartile. In the sensitivity analysis, a significant reduction in the risk of MetS was also found in the fourth quartiles (OR, 95%CI: 0.67, 0.51-0.89; 0.63, 0.46-0.85; 0.74, 0.56-0.98) compared with the first quartile when excluding smokers, alcohol users, and underweight/obesity, respectively. And there was no association between dietary fructose intake and the risk of MetS after multivariate adjustment stratified by gender, smoking and alcohol use.

**Conclusions:** Under the current dietary fructose intake status, there was no association between dietary fructose intake and the risk of MetS among Chinese residents aged 45 and above. Physical activity and relatively low fructose intake may have a beneficial synergistic effect on MetS.

## Introduction

Metabolic syndrome (MetS) refers to a series of cardio-metabolic risk factors leading to high risk for developing cardiovascular disease, type 2 diabetes, non-alcoholic fatty liver, and chronic kidney disease. Its symptoms include abdominal obesity, hyperglycemia, hypertension, and dyslipidemia (1, 2). Over the past few decades, the prevalence of MetS has increased dramatically and has become one of the major public-health challenges in China and worldwide (2-4). The overall standardized prevalence of MetS was 24.2% among Chinese adults, and over 32% for those who aged 45 and above (5).

Increased sugar intake was widely recognized as a contributor to the worldwide epidemics of obesity, diabetes, and their associated cardio-metabolic risks (6). Due to its unique set of biochemical, metabolic, and endocrine responses, fructose was regarded as the main bad factor in sugars and associated with all the key features of MetS (6, 7). A series of systematic reviews and meta-analysis discussed the relationship between fructose and components of MetS. Some of them concluded that intakes of fructose were associated with increased risk of obesity, dyslipidemia, hypertension and cardiometabolic

syndrome (8-11). However, some of them found that a certain dose of fructose have no adverse or even some positive effects on fasting glucose, blood pressure, and blood lipids (12-16). Most of the studies included in these meta-analyses were interventional studies with high-dose fructose intake. In the “real world” study, a cross-sectional population-based research on Iranians reported that higher consumption of dietary fructose increased the risk of MetS, while no such association was found in the US population (17, 18). Differences in dietary intake may be an important reason for the different results. Our previous research found that the average dietary fructose intake of Chinese residents aged 45 and above was 8.29 g/d, which is lower than that of Americans (48.07 g/d) and Iranians (46.50 g/d for male and 37.30 g/d for female) (19). Up to now, there is no large epidemiological study to explore the relationship between dietary fructose and MetS under the current intake level among Chinese population although the prevalence of MetS has increased sharply.

Based on data of nationally representative cross-sectional survey of China National Nutrition and Health Survey (CNNHS) in 2010-2012, this study aims to investigate the effect of dietary fructose intake on MetS among Chinese residents aged 45 and above. Furthermore, we stratified analyzed the variables (gender, physical activity, smoking, and alcohol use) that might influence the risk of MetS.

## **Materials And Method**

### ***Study Design and Subjects***

The nationwide representative cross-sectional study of CNNHS was conducted between 2010 to 2012 by Chinese Center for Disease Control and Prevention to assess the nutrition and health status of Chinese population. This survey covered all 31 provinces, autonomous regions, and municipalities directly under the Chinese central government (excluding Taiwan, Hong Kong, and Macao). A stratified multistage random cluster sampling method was conducted at 150 surveys sites of 4 types: 34 large cities, 41 small-to-medium cities, 45 general rural areas and 30 poor rural areas. The survey procedure has been described in detail elsewhere (20). All participants were supposed to undergo three consecutive 24-h dietary records combined with food weighting, survey questionnaires, physical examination, and fasting blood collection.

In this study, we included participants aged 45 and above with complete demographic information, medical history, lifestyle factors and dietary intake data. We excluded those with implausible energy intakes (< 800 kcal/day or > 4800 kcal/day for male and < 500 kcal/day or > 4000 kcal/day for female). A total of 25528 participants (11574 males and 13954 females) were included (20).

This survey was ethically approved by the Ethical Committee of the National Institute for Nutrition and Food Safety, Chinese Center for Disease Control and Prevention (2013-018). Written informed consent was obtained from all participants.

### ***Data collection and definition***

Data were collected by trained health workers or nurses in health examination centers from local health stations or community clinics according to a standard protocol. Questionnaires including demographic information, medical history, and lifestyle factors, were conducted by trained interviewers. Marital status was categorized into three statuses (single, married, divorced/widowed). We classified education level into primary schools or below, junior high school, senior high school, and college or above. Smoking was defined as “having smoked 100 cigarettes during lifetime” and “current smoking”. Alcohol was referred to as “alcohol intake more than once per month during the past 12 months”. Physical activity was defined as “moderate physical activity for more than 10 minutes at least once per week” (21). According to the grading standards of national residents’ net income levels by National Bureau of Statistics in 2009, high income was defined as “ $\geq 20000$  per person per year for urban residents or  $\geq 10000$  for rural”, middle income as “15000 ~ 19999 for urban or 5000 ~ 9999 for rural”, and low income as “ $< 15000$  for urban or  $< 5000$  for rural”.

Height, weight, waist circumference (WC) and blood pressure (BP) were measured in the morning with standardized procedures. Height was measured in bare feet to the nearest 0.1cm. Weight was measured in standing position and light clothing to the nearest 0.1 kg. Body mass index (BMI) was calculated with weight (kg) being divided by height (m) squared. WC was measured in standing position between the lower edge of the costal arch and the upper edge of the iliac crest. BP levels were measured for 3 times in succession with 1-minute interval between the measurements, with a standard mercury sphygmomanometer at the nondominant arm in sitting position after 5 minutes of rest. Systolic blood pressure (SBP) was measured at the first appearance of a pulse sound (Korotkoff phase 1) and diastolic blood pressure (DBP) at the disappearance of the pulse sound (Korotkoff phase 5). The mean of the three measurements was used for analysis.

### ***Dietary Data and Assessment of Dietary fructose intake***

Data as individual dietary records and household food consumptions were collected over three consecutive days. Individual dietary data including all foods consumed at home and away from home (type, amounts, type of meal, and place of consumption) were collected by trained dietary investigators. Weighting method was used to assess household food consumptions, which includes all foods and condiments. The Chinese Food Composition was used to calculate individual daily intake of energy, protein, fat, and carbohydrate contained by each food item in the dietary data.

Since there was no fructose content data in the Chinese Food Composition (1460 food items), we used fructose content data of the American Food Composition Database (2183 food items) and Chinese Sugar Content Database in Pre-packaged Foods (363 food items) to assign the value of fructose content for each food item (22, 23). The principle of food fructose content assignment was described in detail in our previous study (19).

Dietary total fructose was composed of free-fructose and bound-fructose. Free-fructose intake for each person was calculated from dietary supplement and natural food intake. Bound-fructose intake for each person was calculated by using one-half of dietary total sucrose, because fructose accounts for one-half

of the sucrose molecule. The intake of all forms of fructose as food-fructose and food-sucrose were summed to give the total intake of fructose for each participant within based on a food-grouping system (17).

According to the major ingredients of foods listed within the food-grouping system used in the Chinese Food Composition Table, all foods were divided into 13 categories: grain and grain products; fruits and fruit products; vegetables and vegetable products; milk and milk products; meat, poultry, fish, and related products; eggs and egg products; legumes and legume products; nuts, seed, and related products; sugars and sweets; nonalcoholic beverages; alcoholic beverages; snacks; and miscellaneous foods.

### ***Anthropomorphic and Blood Biochemical Methods***

Blood samples were collected by trained nurses from all participants undergoing an overnight fast for at least 10 hours. Samples were centrifuged at 1500 rpm for 10 minutes after being left standing for 30 to 60 minutes. The centrifuged serum sample were transported to the central laboratory of the National Institute for Nutrition and Health and stored at -80 degrees centigrade. Procedure, processing, and determination for the blood collection were standardized. Fasting plasma glucose (FPG), total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C) and triglycerides (TG) were measured by a Hitachi automatic biochemical analyzer with reagents from Wako Pure Chemical Industries, Ltd (Tokyo, Japan).

### ***Definition of MetS***

According to the recommendation from the International Diabetes Federation and Chinese Diabetes Society criteria (24, 25), a person who met three or more of the following five criteria were diagnosed as MetS: (1) abdominal obesity (WC  $\geq$  90 cm in male or  $\geq$  85 cm in female); (2) hyperglycemia (FPG  $\geq$  6.1 mmol/L or diagnosed diabetes); (3) hypertension (SBP  $\geq$  130 mmHg or DBP  $\geq$  85 mmHg or diagnosed hypertension); (4) TG  $\geq$  1.70 mmol/L; (5) HDL-C  $<$  1.04 mmol/L.

### ***Statistical Analysis***

Data were collected with specialized software, and data cleaning and statistical analyses were performed by using SAS version 9.4 (SAS Institute Inc., Cary, NC, USA). Due to the differences of total dietary fructose intake and the prevalence of MetS between urban and rural areas, analyses were separately performed in regard with urban and rural samples. Categorical variables were presented as percentage (95% confidence interval, 95%CI) and examined with a chi-square test. Continuous variables with normal distribution were presented as mean (95%CI) and were compared across groups with z test. Skewed distribution variables were indicated with quartiles and were examined by non-parametric statistical hypothesis test. The Cochran and Mantel-Haenszel test were used to analyze the characteristics of normal and MetS in urban and rural areas. Univariate and multivariable-adjusted logistic regression were performed to explore the association between dietary fructose intake and risk of MetS. The first quartile of dietary total fructose intake was set as the reference. Three models were involved in this study: model 1 did not adjust any variables; model 2 adjusted for gender, age, education, marital status, smoking,

alcohol, physical activity, income, energy, protein, fat, carbohydrate, and TC; model 3 adjusted for all variables in model 2 plus BMI. Odds ratios (OR) and 95%CI were measured. A value of  $P < 0.05$  was considered statistically significant.

## Results

### *Basic Characteristics of the Study population*

A total of 25528 participants were included in the study with an average age of 59.1 years. Among these, 13067 (44.1% males) were urban residents and 12461 (46.6% males) were rural residents. There were significant differences between urban and rural participants regarding age, gender, marital status, education, smoking, alcohol, physical activity, and income. BMI, WC, TC, TG, and FPG were higher in urban than in rural participants ( $P < 0.001$ ), whereas HDL-C was the opposite ( $P < 0.001$ , Table 1). Table 2 shows that the prevalence of MetS in urban areas was 32.4%, higher than that in rural 24.7% ( $P < 0.001$ ).

***Dietary Fructose Intake Level and Food Sources***

The average daily dietary total fructose intake for urban residents was 11.6g and 7.6g for rural residents. Dietary total fructose intake level was significantly higher in urban residents than that in rural residents, as well as free-fructose and bound-fructose levels ( $P < 0.001$ ). Intakes of protein and fat were significantly higher in urban residents while energy and carbohydrate were higher in rural residents ( $P < 0.001$ ). Table 3 shows the basic characteristics of dietary fructose and nutrients with mean and quartiles.

**Table 3** Intake status of dietary fructose and nutrients in urban and rural residents

	City				Rural				p-Value
	Mean	P <sub>25th</sub>	Median	P <sub>75th</sub>	Mean	P <sub>25th</sub>	Median	P <sub>75th</sub>	
Total Fructose, g/d	11.6	4.8	8.3	14.5	7.6	3.4	5.3	8.8	<0.001
Free-Fructose, g/d	6.7	2.2	4.2	8.4	4.6	1.6	2.7	5.1	<0.001
Bound-Fructose, g/d	4.9	2.4	3.7	6.0	3.1	1.6	2.4	3.7	<0.001
Energy, kcal/d	1887	1454	1780	2204	2159	1648	2041	2547	<0.001
Protein, g/d	61.2	44.8	56.6	72.5	59.3	43.6	55.4	71.2	<0.001
Fat, g/d	76.1	50.2	69.2	94.1	70.8	44.0	64.0	90.2	<0.001
Carbohydrate, g/d	240.3	178.0	224.9	284.3	322.7	238.7	299.4	378.7	<0.001

We further investigated the food sources of dietary fructose. Fruits and fruit products, vegetables and vegetable products, and snacks were the top three food sources for dietary fructose among urban residents accounting 69.02% for the total dietary fructose intake, while vegetables and vegetable products, Fruits and fruit products, and grain and grain products were the top three food sources for dietary fructose in rural residents contributing 73.45% to the total dietary fructose intake (Figure 1). Food sources of total dietary fructose in urban and rural areas with mean and quartiles were shown in table S1.

***The Association between Dietary Fructose Intake and Risk of MetS***

For urban residents, in addition to FPG, there were significant differences in WC, SBP, DBP, TG and HDL-C between the quartiles. The prevalence of MetS was higher in the third quartile than that in the first and forth quartiles ( $P < 0.05$ ). For rural residents, we found significant differences in FPG, SBP, DBP, TG, and

HDL-C between the quartiles except for WC. There was no significant difference in the prevalence of MetS between quartiles (Table 4).

**Table 4** Basic characteristics of components of MetS by the quartiles of dietary fructose intake

Compared with the first quartile, the risk of MetS was increased in the third quartile among urban residents (OR: 1.13; 95%CI: 1.02-1.26). After adjusting confounding factors (gender, age, education, marital status, smoking, alcohol, physical activity, income, energy, protein, fat, carbohydrate, TC and BMI), no statistical significance was found. For rural residents, regardless of adjustments made for confounding factors, no association between dietary fructose intake and the risk of MetS was found (Table 5).

### ***Stratified analysis of the Association between Dietary Fructose Intake and Risk of MetS***

We further analyzed the association between dietary fructose intake and the risk of MetS stratified by gender, physical activity, smoking, and alcohol use. For urban residents with physical activities, the prevalence, and the risk of MetS decreased with the increase of the quartile levels of dietary fructose intake ( $P < 0.001$ ). Compared with the first quartile, the risk of MetS in the fourth quartile (OR: 0.67; 95%CI: 0.52-0.86) was reduced after adjustment for confounding factors (Table 6). In the sensitivity analysis, we also found a significant reduction in the risk of MetS in the fourth quartile (OR, 95%CI: 0.67, 0.51-0.89;

0.63, 0.46-0.85; 0.74, 0.56-0.98) compared with the first quartile when excluding smokers, alcohol users, and BMI < 18.5 or BMI ≥ 28, respectively (Table 7). For urban residents with no physical activities, the prevalence of MetS increased with the increase of dietary fructose intake ( $P = 0.007$ ). There was no significant difference for the relationship between dietary fructose intake and the risk of MetS after multivariate adjustment, as was the case in the sensitivity analysis (Table 6, Table 7).

Regardless of physical activities for rural residents, there was no association between dietary fructose intake and the risk of MetS (Table S2). When stratified by gender, the prevalence of MetS was the lowest in the first quartile of dietary fructose intake for urban males, but in the fourth quartile for urban females (Table S3). There was no association between dietary fructose intake and the risk of MetS after multivariate adjustment stratified by gender, smoking and alcohol (Table S3, Table S4, Table S5).

## Discussion

In this nationwide representative cross-sectional study, we discussed the association between dietary fructose intake and the risk of MetS among Chinese residents aged 45 and above. The consumption of dietary fructose for urban residents was 11.6 g/day and for rural residents was 7.6g/day. Under the current dietary fructose intake status, we did not find an association between dietary fructose intake and the risk of MetS in both urban and rural residents aged 45 and above. However, there was a significant inverse association between dietary fructose intake and MetS for urban residents with physical activities.

A large number of researches suggested that fructose was a culprit in the occurrence of MetS through several metabolic pathways, such as increasing hepatic *de novo* lipogenesis in the liver(26), depleting ATP stores which results in increasing generation of uric acid via purine pathway(27, 28), affecting on plasma lipids, lipoprotein, and apolipoproteins (29, 30), and host-gastrointestinal microbe interactions (31, 32). However, there were still disputes between mechanism studies and population epidemiological studies. According to the systematic reviews and meta-analysis, high doses of fructose ( $\geq 100\text{g/day}$ ) increases serum TG concentration (10, 33), low to middle doses of fructose (0~90g/day) have a benefit effect in HbA1c (14, 34). But fructose did not increase the risk of hypertension and type 2 diabetes (13, 35), also, it did not affect serum HDL-C concentration (33) and cause weight gain when it was substituted for other carbohydrate in diets providing similar calories (36).

In present study, we did not find an association between dietary fructose intake and the risk of MetS among Chinese residents aged 45 and above. The results of this study were consistent to the study from the NHANES 1999-2006 which showed ordinary fructose consumption (approximately 37% of total sugars and 9% of daily energy in the US population) had no association with the risk of MetS (18). Both two studies were population-based cross-sectional studies. However, a systematic review and meta-analysis discussing the association of fructose consumption and components of MetS reported that fructose consumption was positively associated with FPG, TG and SBP, and negatively associated with HDL-C (9). We assumed several reasons for the difference. On the one hand, the fructose sources were different. Food sources of fructose in this meta-analysis were from industrialized foods. In our study, however, fruits and fruit products, vegetables and vegetable products were the most dominant food sources, accounting for more than 50% of dietary fructose. One study reported that most food sources of dietary fructose (especially fruits) did not have a harmful effect on indicators of health (HbA1c, fasting insulin), but several food sources of fructose (especially sugars-sweetened beverages) adding excessive energy to diets showed negative effects (37). On the other hand, the fructose intake was different. Fructose provided at least 15% of daily energy requirements in the 15 studies included in this meta-analysis. In our study, however, the average dietary fructose intakes for urban and rural residents was 11.6g/day and 7.6g/day, respectively. They contributed less than 3% of energy requirements. Several systematic reviews reported that a continuous exposure to high fructose intake may have adverse health effects (38, 39). The previous study has shown that the percentage of total calories from added sugar containing food of Chinese residents in 2010-2010 was 9.09%, which was under the recommended limits (10%) of WHO (40, 41). In addition, some researchers argued that the before-after design used by the authors, the lack of adjustment for energy as an important confounding variable, and unclear statistical methods render their results as uninterpretable. Under calorie-matched conditions, this systematic review

and meta-analysis cannot infer that fructose uniquely affects most components of MetS (42). In this study, we not only adjusted the confounding factors, including energy, but also stratified analyzed the variables (gender, physical activity, smoking, and alcohol use) that might influence the risk of MetS.

Interestingly, we found that the risk of MetS decreased with the increase of the quartile levels of dietary fructose intake for urban residents with physical activities. In recent years, a growing number of researches supported the idea that physical activities might play a role of modulator for fructose's health effects (38, 39, 43-45). Fructose was generally processed in splanchnic organs (small bowel, liver, kidneys) and turned into glucose, lactate, and fatty acids, which serve as metabolic energy substrates in extra-splanchnic organs and tissues (38). As fructose uptake and fructolysis were unregulated processes, the amount of metabolic energy substrates was proportionate to fructose intake (43). For sedentary subjects, high fructose intake caused an overflow of metabolic energy substrates which resulted in increased gluconeogenesis, *de novo* lipogenesis, and triglyceride-rich lipoprotein secretion in the liver (43). In contrast, for physically active subjects, a high fructose intake will be accompanied together by high energy expenditure, fructose in this way would be mainly metabolized into glucose and lactate that can be readily oxidized to support ATP synthesis, resulting in a net lactate release from splanchnic organs (mostly the liver) to the working muscle (43). This 'reverse Cori cycle' may be advantageous to improve performance by acting on central fatigue and/or alter metabolic regulation (44, 45). An animal study showed that the naked mole-rat can resist hypoxia and acidosis by increasing fructolysis (46). In our study, dietary fructose intake in the fourth quartile of urban and rural residents was 25.6g/day and 16.8g/day, respectively, both of which were in relatively low dosage. A series of systematic reviews and meta-analyses have reported that small doses of fructose, or fructose in substitution for glucose or sucrose, may have beneficial effects or not any adverse effects on the components of the MetS (13-16, 34, 47, 48). Based on the above points, we suggested that physical activities and relatively low fructose intake may have a beneficial synergistic effect on MetS.

Several limitations should be considered in the present study. First, this cross-sectional study has a natural disadvantage to address causal relationship between dietary fructose intake and MetS. Second, fructose additionally supplied was not distinguished in this study. In previous studies, the intake status of additional fructose and its relationship with metabolic disease were the focus of attention. However, the consumption of added fructose was very low in our study population. Third, the accuracy of dietary records was limited as the faint recalling of the participants' dietaries and the specificity with which the reported foods were mapped in the dietary recall records. To minimize this situation, all interviewers completed a strict training program with detailed methodologies on administration of the dietary questionnaire. Forth, three consecutive 24-h dietary records may not reflect long-term dietary habits. More high-quality cohort studies and randomized controlled trials were needed to evaluate the association between dietary fructose intake and the risk of MetS.

## Conclusions

To our knowledge, the present study fills the gap by firstly discussing the association between dietary fructose and the risk of MetS among Chinese residents aged 45 and above. Fruits and fruit products, vegetables and vegetable products were the main food sources, and the dietary fructose intake was relatively low. Under the current dietary fructose intake status, there was no association between dietary fructose intake and the risk of MetS in both urban and rural residents. Interestingly, there was a significant inverse association between dietary fructose intake and MetS for urban residents who participating in physical activity. Our results indicated that physical activity and relatively low fructose intake may have an advantageous synergistic effect on MetS.

## List Of Abbreviations

MetS, metabolic syndrome; CNNHS, China National Nutrition and Health Survey; WC, waist circumference; BMI, body mass index; SBP, systolic blood pressure; DBP, diastolic blood pressure; FPG, fasting plasma glucose; TC, total cholesterol; HDL-C, high-density lipoprotein cholesterol; TG, triglycerides.

## Declarations

**Ethical approval and Consent to participant:** This survey was ethically approved by the Ethical Committee of the National Institute for Nutrition and Food Safety, Chinese Center for Disease Control and Prevention (2013-018). Written informed consent was obtained from all participants.

**Consent for publication:** All authors have read and agreed to the published version of the manuscript.

**Availability of data and materials:** Not applicable.

**Conflicts of Interest:** The authors declare that they have no competing interests.

**Funding:** This work was funded by the Special Funds of Basic Research of Central Public Welfare Institute (No. ZX1902), and the National Natural Science Foundation of China (No. 81703216 and No. 31901698).

**Author Contributions:** The authors contributions were as follow: Conceptualization, J.Z. and W.Q.; methodology, S.P.; software, S.P.; validation, P.S., C.Y., G.S, and Y.W.; formal analysis, S.P.; investigation, S.P, P.S., C.Y., G.S, and Y.W.; resources, J.Z.; data curation, P.S.; writing—original draft preparation, S.P.; writing—review and editing, J.Z. and W.Q.; visualization, S.P.; supervision, J.Z.; project administration, W.Q.; funding acquisition, W.Q.
