Abstract

The simulation and planning system (SPS) requires accurate and real-time feedback regarding the deformation of soft tissues during the needle insertion procedure. Traditional mechanical-based models such as the finite element method (FEM) are widely used to compute the deformations of soft tissue. However, it is difficult for the FEM or other methods to find a balance between an acceptable image fidelity and real-time deformation feedback due to their complex material properties, geometries and interaction mechanisms. In this paper, a Kriging-based method is applied to model the soft tissue deformation to strike a balance between the accuracy and efficiency of deformation feedback. Four combinations of regression and correlation functions are compared regarding their ability to predict the maximum deformations of ten characteristic markers at a fixed insertion depth. The results suggest that a first order regression function with Gaussian correlation functions can best fit the results of the ground truth. The functional response of the Kriging-based method is utilized to model the dynamic deformations of markers at a series of needle insertion depths. The feasibility of the method is verified by investigating the adaptation to step variations. Compared with the ground truth of the finite element (FE) results, the maximum residual is less than 0.92 mm in the Y direction and 0.31 mm in the X direction. The results suggest that the Kriging metamodel provides real-time deformation feedback for a target and an obstacle to a SPS.

Keywords: Kriging metamodel; needle insertion; real-time simulator; soft tissue deformation

1 Introduction

In needle-based minimally invasive surgeries, needle insertion errors always lead to a large probability of serious complications and increase the physical pain of patients [1–4]. Real-time feedback regarding soft tissue deformation during needle insertion, especially in the region around the target and obstacles, and the experience of the attending physicians affect the insertion accuracy [4]. The simulation and planning system (SPS) can provide pre- and intraoperative deformation information and help physicians to sharpen their skills [5], which can effectively improve the success rate of minimally invasive surgeries. Soft tissue visualization during the needle insertion procedure, which is the most important part of the SPS, is realized by a deformation model of the soft tissue [6].

The soft tissue deformation model has been widely studied in the literature [7–11], of which continuum mechanical-based modeling methods such as the finite element method (FEM) are the most popular [11–13]. Dimaio et al. established the soft tissue of a simple geometry using the FEM, in which the refined elements along the needle path were configured and the interaction force was experimentally loaded onto the node path. The material properties of the tissue were modeled as the linear elasticity [13]. Misra et al. [14] reviewed and sorted out the tool-tissue interaction models based on the tissue material properties, which revealed that the hyperelastic model had a relatively high accuracy. Kobayashi et al. modeled the nonlinear and viscoelastic liver based on the finite element method [15]. The complicated organ geometry and boundary conditions were taken into account in [16,17]. The complex boundary conditions and geometry of real organs, as well as the viscoelastic and heterogeneous material properties, increased the computational complexity.

Furthermore, the needle insertion process includes material failure and a new internal surface formation; thus, the underlying physics is also an essential part. Some of the traditional FEM modeling methods, although able to provide fast calculations of tissue deformation, lead to unpleasing visual results during the needle insertion procedure due to their rough simplification of the needle puncture process. Takabi [18] presented a comprehensive survey mainly on the modeling of tissue cutting, focusing on the mechanical concepts and modeling techniques. Gokgol et al. [19] modeled the FEM cutting process by defining a fracture work, the nodal in the FEM model break when the cutting energy exceeded the fracture work. The thresholds can also be other failure parameters such as the maximum shear strain [20]. Oldfield and Dini used cohesive elements in the ABAQUS commercial software to describe the material failure [21]. However, all of these methods require the elements along the needle path to be sufficiently small, which may result in a large computational burden and instability in the calculations. Recently, the extended finite element method (X-FEM), typically utilized for crack propagation, was also applied to soft tissue cutting [22]. It reserved the initial mesh topology without very high-resolution grids in modeling the discontinuities, but an appropriate enrichment function was difficult to establish. To eliminate the mesh dependence in the traditional FEM, the meshless method was proposed for soft tissue deformation modeling, which is particularly suitable for simulating large deformation and cutting processes since it is not required to calculate equations on the grid [23,24]. However, the basis interpolation function in the meshless method is complex and consumes too many computing resources.

A successful surgery simulation and planning system requires two contradictory basic processes: physical reality and real-time dynamic interaction. However, most existing needle insertion deformation models with high accuracy during needle insertion are simulated offline. It is difficult for the FEM or other methods to balance the acceptable image fidelity and real-time deformation feedback, which limits their applications in real clinical trainings [25, 26]. In this paper, a Kriging metamodel is applied to model and predict the deformation of obstacles and targets inside soft tissue during the needle insertion procedure. The Kriging metamodel was addressed by the South African mining engineer Krige and developed by Matheron, a French mathematician [27]. It is a simplified computer-based simulation model that has
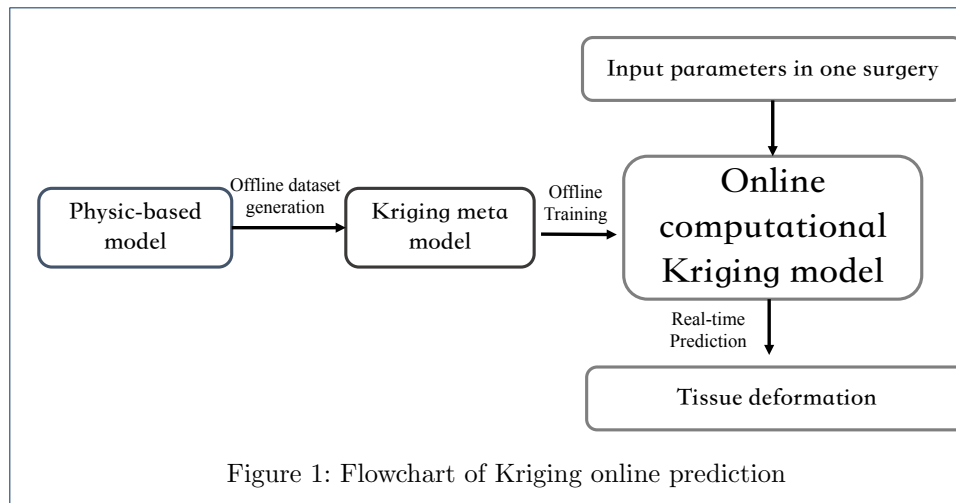

an input/output function based on the surface response [28]. The advantages of the Kriging metamodel are twofold: First, the Kriging metamodel can reduce the large requirement for computing resources and offer real-time simulation, especially being able to overcome the challenges of computational techniques in complex simulation models [29]. Hence, depending on the accurate simulation dataset generated by other offline needle-tissue interaction models, the online Kriging model can be established rapidly without reducing the accuracy of the original model by much. Second, the computer-based simulation program is deterministic, that is, the same input corresponds to the same output, which cannot fully reflect the uncertainty of mechatronic systems [30, 31]. In robot-assisted needle insertion systems, complex factors such as the imaging equipment, physician's skill and patient's condition lead to uncertainty regarding tissue deformation. The Kriging metamodel with the random sampling method can reflect the uncertainties of robot-assisted needle-tissue interactions.

In our work, the input dataset is generated by Latin hypercube sampling (LHS), the parameters of which include the material properties of the tissues and needle, the geometrical properties of the needle and the solver parameters. Ten characteristic markers are selected to represent the targets and obstacles inside the tissue body. The output dataset is generated by running the needle-tissue coupling FE model presented in [32], which is used as the ground truth of the Kriging-based model. The validity and feasibility of the proposed Kriging-based model are analyzed, and the results suggest that the combination of the Kriging metamodel and the high-precision finite element model provides real-time deformation feedback for a target and an obstacle to the SPS.

The rest of this paper is organized as follows. Section II introduces the data preparation, the basic theory of the Kriging model and the maximum deformation modeling of needle insertion at a fixed depth. In Section III, the functional-based Kriging model is applied to establish the deformation model at a series of depths, of which the adaptation to the step variation is also analyzed. Section IV discusses the proposed Kriging model. Finally, conclusions and future work are given in Section V.

Flowchart of Kriging Deformation Online Prediction

A flowchart of Kriging online deformation prediction is shown in Fig.1. In offline process, a physic-based model, such as finite element based needle insertion model is utilized to generate dataset. The dataset include the input parameters and output deformations in different locations. The input parameters include material parameters of soft tissues, needle parameters and other parameters affecting the deformation results obviously. The dataset is provided and offline trained for Kriging meta model. Training process is for tuning Kriging parameters to best fit the deformation prediction model. Kriging model is in essence a computational model; thus, it can realize real-time prediction while maintain the accuracy of the physic-based model. In surgery simulation and planning, when input current parameters of tissue and needle, the Kriging model can online predict soft tissue deformation for surgery training or needle path planning.

Deformation Modeling of Needle Insertion at a Fixed Depth

A finite element model for the needle-tissue interaction was built by our group to simulate tissue deformation [32]. In this paper, we aim to predict the motion of the target and obstacles inside the tissue in real time. To test the validation of the Kriging-based prediction model, ten characteristic markers in the FE model are selected as the observation points, as shown in Fig. 2. The observation points are chosen according to the distance from the needle body. The points near the needle body include N1 $(-0.0064, -0.0256)$, N2 $(0.0052, -0.0238)$, N3 $(-0.0058, -0.0445)$, N4 $(0.0054, -0.0447)$, N5 $(-0.0068, -0.0629)$ and N6 $(0.0041, -0.0641)$, which represent locations near the needle but at different insertion depths, wherein points 1, 3, and 5 are distributed on the left side of the needle body and 2, 4, and 6 are distributed on the right side. They are not symmetrical about the needle body even though they are distributed bilaterally, as the needle will bend as the insertion depth into the soft tissue increases due to the beveled needle tip, as shown in Fig. 2. Observation points N7 $(-0.0254, -0.0232)$, N8 $(-0.0485, -0.0228)$, N9 $(-0.0290, -0.0637)$ and N10 $(-0.0501, -0.0649)$ are far from the needle body, wherein 9 and 10 are also near the fixed boundaries.

There were 11 variables chosen and listed in Table 1, wherein x1, x2, and x11 are the material parameters of soft tissues, x3 - x7 are the needle parameters, x8 - x9 are the FEM solver parameters and x10 is the friction coefficient between the needle and soft tissue.

The input variables are denoted as $X = [x_1, \cdots, x_{11}]$, which are employed to construct the design matrix of the Kriging-based model. Running the finite element model 20 times, the displacements at the 10 observed locations are collected as the output responses of the Kriging model, denoted by $Y = \left[u_{xy}^1, \cdots, u_{xy}^{10}\right]^T = [y_1, y_2, \cdots, y_{10}]^T$, $y_i \in \mathbf{R}^{20}$. The soft tissue deformation occurs in both the x and y directions in the two-dimensional case; hence, the output response u_{xy} is the resultant displacement in both directions and is written as

$$u_{xy} = \sqrt{u_x^2 + u_y^2}, \tag{1}$$

Figure 2: 10 observation points in the needle insertion procedure for the Kriging-based model

Table 1: Factors and range of values in the soft tissue deformation experiment

Variable	Factor	Range	
		Maximum Value x_L	Minimum value x_U
x_1	Young's modulus of the soft tissue	10 KPa	50 KPa
x_2	Soft-tissue Poisson ratio	0.3	0.5
x_3	Tip angle	$0°$	$90°$
x_4	Needle penetration angle	$-15°$	$15°$
x_5	Needle radius	0.2 mm	0.6 mm
x_6	Needle length	100 mm	250 mm
x_7	Young's modulus of the needle	200 GPa	300 GPa
x_8	Rayleigh coefficient of damping α	0.01	0.1
x_9	Rayleigh coefficient of damping β	0.01	0.1
x_{10}	Coefficient of friction	30 N/m	50 N/m
x_{11}	Area density	20 kg/m^2	30 kg/m^2

where u_x and u_y are the displacements in the x and y directions, respectively. Since the resultant displacement increases as the needle insertion depth into the tissue increases, the maximum value of u_{xy} is chosen as the output response of the Kriging-based prediction model.

Kriging model construction

The Kriging prediction model is an interpolation of known observation locations, of which the mean square error equals zero. The Kriging model is usually expressed as a combination of a polynomial and its deviation [33], written as

$$\hat{y}(x) = f^T(x)\beta^* + r^T(x)\gamma^*, \tag{2}$$

where $f(x)$ is the basis polynomial function, usually a regression function. $r(x)$ is the column vector of correction matrix $\mathcal{R}_{m \times m} = [R(x_i, x_1), R(x_i, x_2), \cdots, R(x_i, x_m)]^T$, $i = 1, 2, \cdots, m$. The coefficients are calculated as $\beta^* = \left(F^T R^{-1} F\right)^{-1} F^T R^{-1} Y$,

$\gamma^* = R^{-1}(Y - F\beta^*)$, where F is the design matrix, written as

$$F_{m \times p} = [f(x_1), f(x_2), \cdots, f(x_m)]^T. \tag{3}$$

m is the number of groups of FE model, and in this application, $m = 20$. p is the number of basis functions, which is determined by the type of basis function. In our experiments, p $= 12$ for first order regression functions. The variable x_i is obtained from the FE model by the Latin hypercube sampling method, and x_i is normalized to the interval $[0, 1]$, as in

$$\tilde{x}_i = \frac{x_i - x_L}{x_U - x_L}, \quad \tilde{x}_i \in [0, 1], \tag{4}$$

where $\tilde{x}_i$ is the normalized data of x_i and x_L and x_U are the minimum and maximum values of the variable x_i, respectively.

The mean square error of the Kriging prediction model is formulated as (5) [34]

$$\varphi(x) = \sigma^2 \left(1 + u^T (F^T R^{-1} F)^{-1} u - r^T R^{-1} r\right), \tag{5}$$

where $u = F^T R^{-1} r - f$ and $\sigma^2 = \frac{1}{m}(Y - F\beta^*)^2 R^{-1}(Y - F\beta^*)$ is the maximum likelihood estimate of the variance.

Regression function

The design matrix $F_{m \times p}$ in the Kriging prediction model is

$$F_{m \times p} = \begin{bmatrix} f_1(x_1) & \cdots & f_p(x_1) \\ \vdots & \ddots & \vdots \\ f_1(x_m) & \cdots & f_p(x_m) \\ , & & \end{bmatrix}_{m \times p}, \tag{6}$$

where the basis function $f(x)$ has several forms. Usually, constant and linear forms of the regression function are used to construct the basis function [35].

- Constant form, $p = 1$, of which the design matrix F is a column vector.

$$f_1(x) = 1 \quad x \in \mathbf{R}^n \tag{7}$$

- Linear form, $p = n + 1$, of which the basis function is written as (8).

$$f_1(x) = 1, f_2(x) = w_1, \cdots, f_p(x) = w_n \quad x \in \mathbf{R}^n \tag{8}$$

where the component form of the estimate point x is expanded as $x = [w_1, w_2, \cdots, w_n] \in \mathbf{R}^n$. In our experiment, both zero order (constant form, p=1) and first order (linear form, p=12) functions are adopted and compared.

138 Correlation function

The Kriging model assumes that the correlation of the output is determined by the distance between the input variables. The correlation function of the input variables is written as the product of n one-dimensional correlation equations, as shown in (9):

$$R(w, x) = R(\theta, w, x) = \prod_{j=1}^{n} R_j(\theta, d_j),\tag{9}$$

where $d_j = w_j - x_j$ and θ is the correlation coefficient. In the Kriging model, the most widely used correlation model is that shown in (10):

$$R(\theta, w, x) = \prod_{j=1}^{n} \exp\left(-\theta_j \|d_j\|^p\right),\tag{10}$$

where $\| \cdot \|$ denotes the Euclidean distance of d. When $p = 1$ and $p = 2$, the exponential and Gaussian correlation functions are as shown in (11) and (12).

$$R_j(\theta, d_j) = \exp\left(-\theta_j \|d_j\|\right)\tag{11}$$

$$R_j(\theta, d_j) = \exp\left(-\theta_j \|d_j\|^2\right)\tag{12}$$

The correlation function decreases with the increase in the Euclidean distance d_j, and a larger correlation coefficient θ leads to a rapid decline of the correlation function. Substituting the correlation function into (5), the mean square error is a function of the covariance σ^2 and the correlation coefficient θ. The optimal solution to the correlation coefficient θ^* is converted into an unconstrained global optimization problem [36], as shown in (13):

$$\theta^* = \arg\min_{\theta} \left[\psi(\theta) \equiv |R|^{\frac{1}{m}} \sigma^2\right],\tag{13}$$

139 where $|R|$ is the determinant value of the correlation matrix R.

140 Deformation Modeling of Needle Insertion at a Fixed Depth

The input and output data are prepared by running the finite element program 20 times, as in [32]. To establish a Kriging model, 19 sets of observation points ($[X_{\text{in}}(1,:)$, $\cdots, X_{\text{in}}(i-1,:), X_{\text{in}}(i+1,:), \cdots, X_{\text{in}}(20,:)]$) are chosen as the input design sites, and the remaining set $X_{\text{in}}(i,:)$ is used as the test set. The zero order and first order regression functions and the Gaussian and exponential correlation functions are employed to construct the Kriging model for static soft tissue deformation. In this section, the maximum displacements of the marked points are regarded as the static soft tissue deformations. Therefore, there are four kinds of Kriging model, namely, zero order Gaussian, zero order exponential, first order Gaussian and first order exponential, which are shown in Fig. 3. In the figure, the experimental values
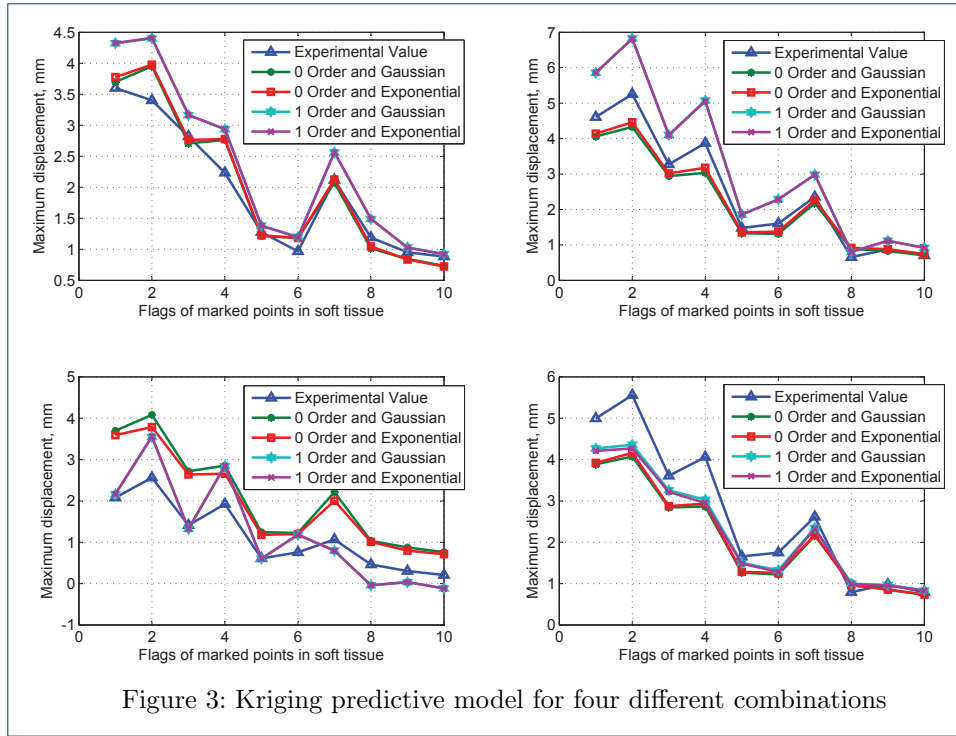

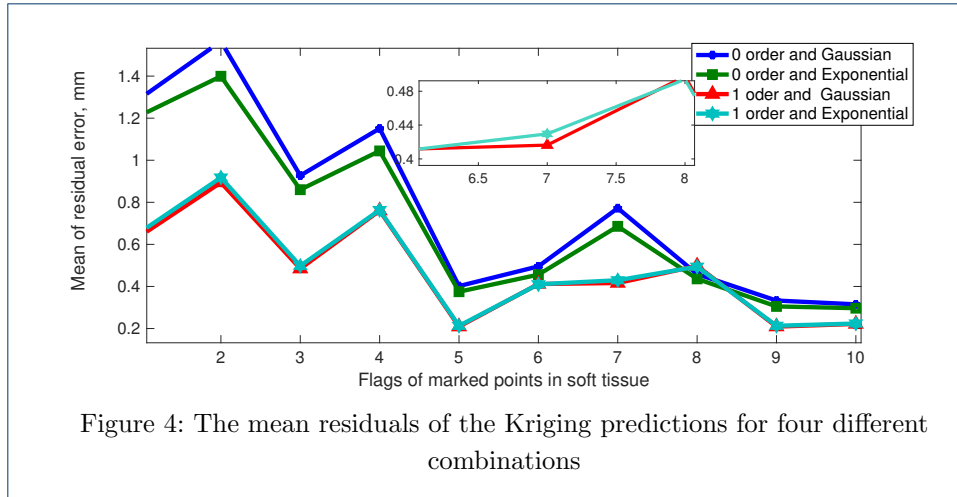

Figure 3: Kriging predictive model for four different combinations

represent the finite element simulation results. The abscissa indicates the number of observation locations, and the ordinate is the value of the maximum resultant displacement. The test set of each run is randomly selected. The upper-left test set is $X_{\text{in}}(5,:)$, the upper-right test set is $X_{\text{in}}(6,:)$, the lower-left test set is $X_{\text{in}}(7,:)$, and the lower-right test set is $X_{\text{in}}(8,:)$. From Fig. 3, it is also suggested that the closer the tissue is to the needle body, the greater the deformation. To analyze the impacts of the regression function and correlation function on the model, the residual $\mathbf{e}$ of the simulation is defined as the difference between the finite element simulation value y and the Kriging prediction value $\hat{y}$, that is, $\mathbf{e} = \hat{y} - y$. The maximum residual values of the zero order Gaussian, zero order exponential, first order Gaussian and first order exponential Kriging models are 7.5108 mm, 7.3327 mm, 3.2752 mm and 3.2994 mm, respectively. Furthermore, the mean residual of each output response is defined as in (14):

$$\bar{\mathbf{e}}_{\text{i}} = \frac{1}{\text{m}} \sum_{j=1}^{\text{m}} |\mathbf{e}_{j\text{i}}| = \frac{1}{\text{m}} \sum_{j=1}^{\text{m}} |\hat{y}_{j\text{i}} - y_{j\text{i}}|, \tag{14}$$

where m is the number of finite element program samples, i.e., $m = 20$. i is the position number of the marked positions, $\text{i} = 1, \cdots, 10$. The mean residuals of the 10 observed locations are shown in Fig. 4. In Fig. 4, the mean residuals of the zero order Gaussian and exponential types are 1.5650 mm and 1.3992 mm, respectively. The mean maximum residuals of the first order Gaussian and exponential are 0.8941 mm and 0.9177 mm, respectively. From the prediction results, the first order regression function is better than the zero order regression function, and the Gaussian correlation function is slightly better than the exponential function from

Figure 4: The mean residuals of the Kriging predictions for four different combinations

the enlarged part. The relative mean residual is defined as shown in (15):

$$\varepsilon = \frac{\bar{\mathbf{e}}_i}{\frac{1}{m} \sum_{j=1}^{m} |y_{ji}|}.$$
(15)

141 Sensitivity analysis of the parameters

142 The Kriging-based prediction model of soft tissue deformation takes into account
143 the 11 input parameters in the finite element simulation process, and the effect of
144 the parameters $X = [x_1, x_2, \cdots, x_{11}]$ on the tissue deformation $Y = [y_1, y_2, \cdots, y_{10}]$
145 is investigated with the first order Gaussian Kriging-based prediction model in this
146 section.

147 In this section, the 'local' sensitivity for each variable is investigated, i.e., only
148 one column is varied for each row selected, while the other columns are fixed. Since
149 the 20 groups sample is randomly generated, there is no specific law for the order
150 of rows. Hence, we construct the parameter test matrix by randomly selecting the
151 four rows of data $X(1, :)$, $X(7, :)$, $X(13, :)$ and $X(18, :)$. The varied variable is evenly
152 distributed in the interval [0, 1] (the interval is divided into 100 equal parts), while
153 the other input variables retain the same values.

154 The sensitivity of parameters is reflected by the average sensitivity index (SI),
155 which is the average change in the output response and input variable of the four
156 selected groups of samples, that is, $SI = \frac{1}{4} \sum_{k=1}^{4} \Delta u_{xy}^{kj} / \Delta x_{ki} (j = 1, \cdots, 10, i =$
157 $1, \cdots, 11)$. When the output displacement increases with the variables, the SI is
158 greater than zero. In the opposite case, the SI is less than zero. According to the
159 range of the SI, the 11 input variables can be classified into three types, i.e., leading
160 parameters, nonleading parameters and disturbed parameters, as shown in Fig. 5,
161 where the abscissa represents 11 variables and the ordinate represents the SI. Since
162 there are ten observation points inside the tissue, there are also ten sensitivity
163 indices for each variable; thus, we choose a box plot to show the extremum (black
164 line at both ends), the interquartile range (blue box) and the median (red line) of
165 one group of the dataset. We classify the 11 variables into three categories based on
166 the sensitivity index: The leading parameters include Young's modulus of the soft
167 tissue x_1, the soft-tissue Poisson ratio x_2, the needle length x_6 and the coefficient

Figure 5: The effects of the leading inputs on the output responses

of friction x_{10}, of which the absolute value of the median of the SI is larger than 0.5 and the effect on different markers is consistent (indices are either all distributed above or below zero). For example, the SI of x1 is always below zero, which means that the soft tissue deformation decreases as x1 increases. These variables have an obvious impact on the deformation due to the large absolute value of the SI. By contrast, the deformation increases as x2 increases, with x2 having a relatively small impact on the deformation. The disturbed parameters include the angle of the needle tip x_3, insertion angle x_4, Young's modulus of the needle x_7 and area density x_{11}. The effect of the disturbed parameters varies for different markers. For the disturbed parameters, the sensitivity index covers the yellow line, which means that the deformations of some markers increase with the parameters, while some markers decrease. The nonleading parameters include the needle diameter radius x_5 and the Rayleigh damping coefficients α (x_8) and β (x_9), which means that the absolute value of the median sensitivity is less than 0.02. The nonleading parameters affect the output displacement slightly and can be regarded as constants.

Sensitivity analysis of the parameters can offer a thorough understanding of the impacts of the input parameters on soft tissue deformation. To ensure rigor of results, other rows of data are also tried in the same way, and the tendencies and slopes came to the same conclusion. The leading and disturbed input parameters play key roles in predicting tissue deformation, directly affecting the overall trend and accuracy of the prediction results. The nonleading parameters have little effect on the prediction results and can be removed from the input parameters if a better real-time performance and lower accuracy are required in the procedure of needle insertion.

The sensitivity analysis provides a basis for reducing the number of input parameters of the Kriging-based prediction model. For a more complex FE model, such as that for a nonlinear, viscoelastic tissue material, the sensitivity analysis of parameters is beneficial for selecting the optimal input parameters and reducing the computation time.

Deformation Modeling of Needle Insertion at a Series of Depths

Kriging model of the functional response

According to the continuum mechanics, the motion equation of a point inside the tissue $\mathbf{O}$ in the Euclidean space is expressed as (16):

$$\mathbf{X} = \chi(\mathbf{x}, t) \mapsto u = \mathbf{X} - \mathbf{x} = \chi(\mathbf{x}, t) - \mathbf{x}, \tag{16}$$

where $\mathbf{x} = x\vec{i} + y\vec{j} + z\vec{k}$ is the position vector at the initial time, $\mathbf{X} = X\vec{i} + Y\vec{j} + Z\vec{k}$ is the position vector at time t, and $u = u_x\vec{i} + u_y\vec{j} + u_z\vec{k}$ is the displacement of point $\mathbf{O}$ at time t. The displacement of tissue nodes is related to the time and space coordination, and it is a functional response with time and space indices. When the Kriging metamodel is used to solve the functional response problem, the calculation of the correlation coefficient of the maximum likelihood estimation includes the inverse matrix and the determinant of the correlation matrix, which leads to the instability and time complexity of the computation [37]. The Kronecker product is employed to construct the correlation matrix and to reduce the computational burden of the Kriging method [38].

The input variables in the FE simulation experiment are $\mathbf{x} = [x_1, x_2, \cdots, x_n]^T$, $\mathbf{x}_i \in \mathbf{R}^n$, $i = 1, 2, \cdots, m$, and the output response is a function of time t. The output response $\mathbf{y}_i = \left[y_{i_1}, y_{i_2}, \cdots, y_{i_{r_i}} \right]^T$ is recorded at each time $\mathbf{t}_i = [t_{i_1}, t_{i_2}, \cdots, t_{i_{r_i}}]^T$, where r_i denotes the time step. The Kriging model of the functional response is written as (17) on the basis of (2):

$$y(\mathbf{x}, t) = \mathcal{F}(\mathbf{x}, t)\beta + z(\mathbf{x}, t), \tag{17}$$

where $y(\mathbf{x}, t)$ is the output response of the input variable $\mathbf{x}$ at time t. $\mathcal{F}(\mathbf{x}, t) = [f_1(\mathbf{x}, t), \cdots, f_p(\mathbf{x}, t)]^T$ is a set of known polynomial basis functions, where usually $f_1(\mathbf{x}, t) = 1$. β is an unknown basis function coefficient. $z(\mathbf{x}, t)$ is a zero-mean Gaussian random function, the covariance function of which is shown in (18):

$$\begin{aligned} V(\mathbf{x}_1, \mathbf{x}_2) &= cov\left(z(\mathbf{x}_1, t_1), z(\mathbf{x}_2, t_2) \right) \\ &= \sigma^2 R(\mathbf{x}_1 - \mathbf{x}_2, t_1 - t_2). \end{aligned} \tag{18}$$

Assume that the correlation function $R(\mathbf{x}_1 - \mathbf{x}_2, t_1 - t_2)$ is the product of n one-dimensional correlation equations, as shown in (19):

$$R(\mathbf{x}_1 - \mathbf{x}_2, t_1 - t_2) = \left[\prod_{j=1}^{n} R_i(x_{i1} - x_{i2}) \right] R_T(t_1 - t_2), \tag{19}$$

where $R_i(x_{i1} - x_{i2})$ is the correlation function of the ith set of variables and $R_T(t_1 - t_2)$ is the correlation function at time t.

The functional response is assumed to be the $N \times 1$-dimensional vector $Y = [\mathbf{y}_1^T, \mathbf{y}_2^T, \cdots, \mathbf{y}_n^T]^T$, and $N = \sum_{i=1}^{m} r_i$. When the time step is r, then $N = mr$. The

corresponding $N \times n$-dimensional design matrix $X = [X_1, X_2, \cdots, X_N]$ is represented with the Kronecker notation as shown in (20):

$$
\begin{aligned}
X_{N \times n} &= \left[\mathbf{1}_{r_1}^T \otimes \mathbf{x}_1, \cdots, \mathbf{1}_{r_n}^T \otimes \mathbf{x}_n \right]^T \\
&= \begin{bmatrix}
x_{11} & x_{12} & \cdots & x_{1n} \\
\vdots & \vdots & \vdots & \vdots \\
x_{11} & x_{12} & \cdots & x_{1n} \\
x_{21} & x_{22} & \cdots & x_{2n} \\
\vdots & \vdots & \vdots & \vdots \\
x_{m1} & x_{m2} & \cdots & x_{mn}
\end{bmatrix}
\begin{array}{l}
\mapsto \text{Row } 1 \\
\vdots \\
\mapsto \text{Row } r_i \\
\mapsto \text{Row } r_i{+}1 \\
\vdots \\
\mapsto \text{Row N}
\end{array}
\end{aligned}
\tag{20}
$$

where $\otimes$ is the Kronecker product operator and $\mathbf{1}_{r_i}$ is the column vector with length $r_i = 1$. When the time steps are the same, X is an $mr \times n$ matrix. $T = [\mathbf{t}_1^T, \cdots, \mathbf{t}_n^T]^T = [t_1^*, t_2^*, \cdots, t_N^*]^T \in \mathbf{R}^{N \times 1}$ is the corresponding functional space. Combined with equations (2) and (17), the Kriging model of the functional response is written as shown in (21):

$$
\hat{y}(\mathbf{x}, t) = \mathcal{F}(\mathbf{x}, t)\hat{\beta} + R^T(\mathbf{x}, t)\mathcal{R}_{X,\mathbf{t}}^{-1}(Y - \mathbf{F}\hat{\beta}),
\tag{21}
$$

where $\mathcal{F}$ is written as

$$
\begin{aligned}
\mathbf{F} &= [\mathcal{F}(X_1, t_1^*), \cdots, \mathcal{F}(X_N, t_N^*)]^T \\
\hat{\beta} &= \left(\mathbf{F}^T \mathcal{R}_{X,\mathbf{t}}^{-1} \mathbf{F} \right)^{-1} \mathbf{F}^T \mathcal{R}_{X,\mathbf{t}}^{-1} Y \\
R(\mathbf{x}, t) &= [R(\mathbf{x} - X_1, t - t_1^*), \cdots, R(\mathbf{x} - X_N, t - t_N^*)]^T
\end{aligned}
\tag{22}
$$

in which $\mathcal{R}_{X,\mathbf{t}}$ is an $N \times N$ correlation matrix, the elements of which are $R(X_i - X_j, t_i^* - t_j^*)$. The correlation coefficient θ is optimized with (13). The optimization of the correlation coefficient requires a large number of solutions of $\mathcal{R}_{X,\mathbf{t}}^{-1}$ and $|\mathcal{R}_{X,\mathbf{t}}|$ so that the computational cost is extremely high.

In this paper, we consider the functional output on the regular grid, i.e., $\mathbf{t}_1 = \cdots = \mathbf{t}_n = t$, $r_1 = \cdots = r_n = r$. The correlation matrix $\mathcal{R}_{X,\mathbf{t}}$ of the functional response is written as (23):

$$
\mathcal{R}_{X,\mathbf{t}} = \mathcal{R}_X \otimes \mathcal{R}_{\mathbf{t}},
\tag{23}
$$

where $\mathcal{R}_X$ is an $m \times m$-dimensional correlation matrix whose elements are $R(\mathbf{x}_1 - \mathbf{x}_2)$ and $\mathcal{R}_t$ is an $r \times r$-dimensional correlation matrix whose elements are $R_T(t_i - t_j)$. The Gaussian correlation function is used to construct the correlation matrix, and the inverse of the correlation matrix is simplified to $\mathcal{R}_{X,\mathbf{t}}^{-1} = \mathcal{R}_X^{-1} \otimes \mathcal{R}_{\mathbf{t}}^{-1}$. Substituting this matrix into (21), we can write the Kriging model of the functional response as (24):

$$
\hat{y}(\mathbf{x}, t) = \mathcal{F}(\mathbf{x}, t)\hat{\beta} + R^T(\mathbf{x}, t)\mathcal{R}_X^{-1} \otimes \mathcal{R}_{\mathbf{t}}^{-1}(Y - \mathbf{F}\hat{\beta}).
\tag{24}
$$

The computational complexity of the inversion matrix is reduced from $O(n^3 m^3)$ to $O(n^3 + m^3)$ with the Kronecker product operator.

(17) takes account of the coupling effect between the input variable $\mathbf{x}$ and time t. The basis function $\mathcal{F}(\mathbf{x}, t)$ is identified by estimating the average value of the functional response. In the case of $r_1 = \cdots = r_n = r$, we define $\bar{e}_{\cdot j} = \frac{1}{m} \sum_{i=1}^{m} (y_{ij} - \bar{y}_{i\cdot})$ and $\bar{y}_{i\cdot} = \frac{1}{r} \sum_{l=1}^{r} y_{il}$. $\bar{e} = [\bar{e}_{\cdot 1}, \cdots, \bar{e}_{\cdot r}]^T$ and $\bar{y} = [\bar{y}_{1\cdot}, \cdots, \bar{y}_{m\cdot}]$ are fitted as shown in (25).

$$
\begin{aligned}
\bar{e}(t) &= k^T(t)\beta_t + z(t) \\
\bar{y}(\mathbf{x}) &= g^T(\mathbf{x})\beta_x + z(\mathbf{x})
\end{aligned}
\tag{25}
$$

221 The unknown polynomial basis functions $k(x)$ and $g(x)$ are constructed us-
222 ing the regression function. Furthermore, the basis function in (24) is writ-
223 ten as $\mathcal{F}(\mathbf{x}, t) = [1, k^T(x), g^T(x)]^T$, and the matrix $\mathbf{F}$ is expressed as $\mathbf{F} =$
224 $[\mathcal{F}(X_1, t_1^*), \cdots, \mathbf{F}(X_N, t_N^*)]^T$.

225 ### Deformation Modeling of Needle Insertion at a Series of Depths

One hundred sets of input variables are generated with LHS to construct the functional response Kriging model. After the normalized inverse operation, the finite element program runs 100 times to generate the deformations in the X and Y directions at 10 marked points for 31 time steps, as shown in Fig. 2. For needle insertion at a constant speed, the insertion time is replaced with the depth d. Here, the 31 time steps are expressed as $d = [1.0 \text{ mm}, 2.0 \text{ mm}, 5.0 \text{ mm}, \cdots, 89 \text{ mm}]$, and the increment of the insertion depth is 3 mm, except in the first step. Forty sets of data are randomly selected from 100 sets of records and used to construct the functional Kriging prediction model of soft tissue deformation, and an independent set of data is used to test the model. According to the former analysis, the polynomial basis functions are first order regression functions, and the correlation functions are Gaussian random functions. To evaluate the real-time performance of the Kriging module, the mean residual $\bar{\bar{\mathbf{e}}}_i$ and the relative mean residual $\bar{\bar{\varepsilon}}_i$ at each time step (insertion depth) are defined for each observation location, written as (26):
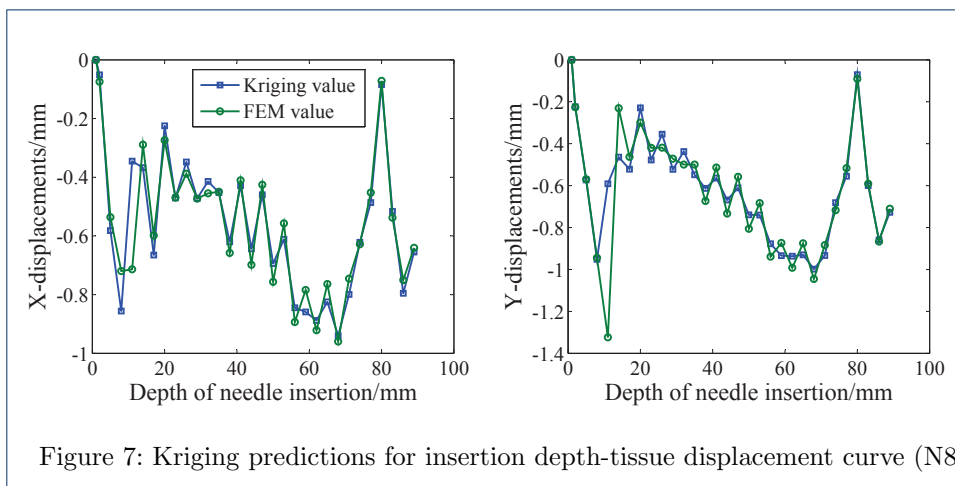

$$
\begin{aligned}
\bar{\bar{\mathbf{e}}}_i &= \frac{1}{r} \sum_{j=1}^{r} |\mathbf{e}_{ji}| = \frac{1}{r} \sum_{j=1}^{r} |\hat{y}_{ji} - y_{ji}| \\
\bar{\bar{\varepsilon}}_i &= \frac{1}{r} \sum_{j=1}^{r} \frac{|\hat{y}_{ji} - y_{ji}|}{|y_{ji}|}
\end{aligned}
\quad ,
\tag{26}
$$

226 where r is the total number of puncturing steps, i.e., r = 31, and i is the position
227 number of the output response, where i $= 1, \cdots, 10$.

228   The procedure of needle insertion is recorded from the time of contact between
229 the soft tissue and the needle tip to the time at which a depth of 90 mm is reached
230 inside the tissue. With the functional response Kriging model, the displacement in
231 the X and Y directions can be predicted, and Fig. 6 plots the displacements of $N2$
232 shown in Fig. 2, which is close to the needle. In Fig. 6, 'Kriging value' denotes
233 the prediction results obtained using the functional response Kriging model, and
234 'FEM' denotes the results obtained with a finite element simulation. From Fig. 6,
235 the displacement fluctuations at the initial and final time steps are relatively large,
236 while the fluctuations between these two time steps are smaller. The functional

Figure 6: Kriging predictions for insertion depth-tissue displacement curve (N2)

response Kriging model follows the law of tissue deformation during the needle insertion procedure. The model can also predict the displacements at other locations at different time steps very well. Fig. 7 shows the displacements at $N8$, which is far away from the needle.

Figure 7: Kriging predictions for insertion depth-tissue displacement curve (N8)

With (26), the mean residuals and relative mean residuals of the 10 locations are as listed in Table 2. Overall, the Kriging model smooths the original finite element

Table 2: Kriging prediction errors at different positions

Error	N1	N2	N3	N4	N5	N6	N7	N8	N9	N10
X_{max}	0.19	0.18	0.13	0.13	0.09	0.09	0.37	0.37	0.23	0.31
Y_{max}	1.24	1.10	0.84	0.76	0.56	0.52	1.06	0.73	0.55	0.52
X_{mean}	0.04	0.03	0.03	0.03	0.02	0.02	0.05	0.05	0.03	0.04
Y_{mean}	0.12	0.11	0.08	0.08	0.07	0.06	0.10	0.07	0.05	0.05
X_{re}	12%	12%	13%	13%	12%	12%	10%	10%	10%	10%
Y_{re}	14%	16%	14%	16%	15%	16%	15%	13%	13%	12%

$*._{max}$ maximum residual. $*._{mean}$ mean residual. $*._{re}$ relative mean residual.

model, and the prediction accuracy of the initial stage is poor. The maximum residuals of the Kriging predictions and finite element calculations in the X and Y directions are 0.37 mm and 1.24 mm, respectively, and both occur in the fifth

246 time step, at which the needle tip punctures the surface of the soft tissue. The
247 average residuals in the X and Y directions occur within 0.05 mm and 0.12 mm,
248 respectively, and the relative mean residual is at most 16%.

249   The runtime is also compared. Both the Kriging model and FEM model run on
250 the same computer with macOS Mojave 10.14.6, a 2.7 Hz Intel Core i5 and 8 GB
251 of RAM, and the program is written in MATLAB 2019b. The average runtime of 5
252 runs is recorded, with the average time for the Kriging-based method being 0.0294
253 s and that of the FEM model being 4.6912 s. Note that neither of the two reported
254 times includes a visualization of the soft tissue deformation process. The reported
255 results indicate that the Kriging model runs approximately 160 times faster than
256 the FEM model.

257 Adaptation of the Deformation Modeling to Step Variations

258 From the above analysis, the Kriging prediction model based on the observations
259 at 31 time steps can reflect the soft tissue deformation at fixed (known) time steps.
260 However, it is necessary to obtain the motion information of the sensitive area inside
261 the soft tissue at any time step for both the path planning and the virtual training
262 system. In this section, the adaptation to different time steps is studied. Additional
263 insertion time steps are expressed as $d_1 = [1.0 \text{ mm}, 2.5 \text{ mm}, 5.0 \text{ mm}, \cdots, 90 \text{ mm}]$, the
264 insertion depth increment is 2.5 mm and the total depth achieved by the needle is
265 90 mm. The displacements of 10 observation locations at d_1 insertion time steps
266 are recorded to compare with the Kriging model. Forty sets of data randomly se-
267 lected from 100 sets of records are used to construct the real-time Kriging prediction
268 model of soft tissue deformation, and an independent set of data is used to test the
269 model. Fig. 8 shows a comparison between the prediction and the computer-based
   experimental results at the $N3$ location. From Fig. 8, the Kriging model with a

Figure 8: Kriging predictions for insertion depth-tissue displacement curve (N3)

270
271 functional response can fit the computer-based experimental results very well and
272 can reflect the fluctuation trends at the initial and end time steps. The maximum
273 residual occurs at the 6th insertion time step, and its maximum residuals and rel-
274 ative mean residuals in the X direction are 0.22 mm and 21%, respectively. The
275 maximum residuals and relative residuals in the Y direction are 0.55 mm and 8%,
276 respectively. The maximum residuals and relative mean residuals of the remaining

Table 3: Kriging prediction errors at different positions

Error	N1	N2	N4	N5	N6	N7	N8	N9	N10
$X_{\max}$	0.31	0.20	0.22	0.16	0.11	0.31	0.29	0.24	0.28
$Y_{\max}$	0.76	0.92	0.55	0.37	0.37	0.51	0.37	0.32	0.29
X_{re}	24%	33%	20%	21%	49%	25%	25%	15%	12%
Y_{re}	6%	7%	7%	8%	7%	6%	6%	6%	6%

*$\cdot_{\max}$ maximum residual, *$\cdot_{\mathrm{re}}$ relative mean residual.

nine observation positions are listed in Table 3. From Table 3, the maximum residual in the X direction occurs at $N1$ and $N7$; its value is 0.31 mm. The maximum residual in the Y direction appears at N2; its value is 0.92 mm. The relative mean residual in the Y direction is less than 8% and has a relatively high accuracy. For the real insertion procedure, the displacements in the X direction are very small, sometimes approaching zero; hence, the relative mean residual is larger than 20%. However, the absolute mean residual of each location is less than 0.31 mm, which can meet the estimation accuracy.

Conclusions and Future Work

In this paper, a computer-based experimental analysis of the Kriging metamodel is presented to predict the deformations of soft tissues. The input data include the material properties of the tissues and needle, the geometrical properties of the needle, and the solver parameters, and they are sampled by the LHS method. The corresponding output dataset is generated by an accurate needle-tissue coupling FE model offline. Ten markers are used to represent the deformations at different positions inside the tissues. Unlike other mechanical-based simulation models, our model can consider both the accuracy and efficiency if high-precision data of the original dataset are well prepared. The results suggest that the proposed Kriging-based model with first order regression and Gaussian correlation functions can well reflect the mechanism of soft tissue deformation. The functional response Kriging-based model can provide feedback regarding deformation at a series of depths for the SPS, of which the time and space indices are both taken into account. The reported time indicates that the Kriging model runs approximately 160 times faster than the original FEM model. Moreover, we also verify that the model has excellent adaptation to step variations. Compared with the ground truth, the maximum residual is less than 0.92 mm, which can satisfy the requirements of the SPS.

The performance of the proposed Kriging-based model depends on the accuracy of the dataset generated by the mechanical-based simulation greatly. Therefore, future work will focus on combinations with a more accurate simulation model, considering complex tissue behavior ranging from hyperelasticity to viscoelasticity, and the needle deflection will be modeled at the same time. The sensitivity of additional parameters will be analyzed to improve the accuracy and efficiency of the Kriging-based model.

Declarations
Availability of data and materials
The datasets analysed during the current study are available from the corresponding author on reasonable request.

Authors' contributions

YL discovered the Kriging based tissue deformation online prediction, ML designed and conducted the sensitivity experiments to find out the effects of different factors and ML assisted with improving the quality of the manuscript. DG interpreted the experimental results. All authors read and approved the final manuscript.

Authors' information

YL received a Ph.D. in Mechanical Engineering from the University of Michigan, Ann Arbor, in 2007. He is currently a professor at the State Key Laboratory of Fluid Power Transmission and Control, Department of Mechanical Engineering, Zhejiang University, Hangzhou. His major research interests include fault diagnosis and maintenance in networked systems, modeling and human-machine interface design for minimally invasive surgery; ML is currently pursuing a Ph.D. at the School of Mechanical Engineering, Zhejiang University, Hangzhou, China. Her current research interests include surgical simulation and robotics; DG received a Ph.D. in Mechatronics Engineering from Zhejiang University, Hangzhou, in 2017 and an M.S. in Mechatronics Engineering from Tsinghua University, Beijing, in 2007. He is currently a professor at the School of Mechanical Engineering, Qinghai University, Xining. His major research interests include computer-aided medical engineering and smart maintenance and operation for a photovoltaic system.
