# Abstract

**Background:** No specific medication has been proven effective for the treatment of patients with severe coronavirus disease 2019 (COVID-19). Here, we tested whether high-dose vitamin C infusion was effective for severe COVID-19.

**Methods:** This randomized, controlled, clinical trial was performed at 3 hospitals in Hubei, China. Patients with confirmed severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection in the ICU were randomly assigned in as 1:1 ratio to either the high-dose intravenous vitamin C (HDIVC) or the placebo. HDIVC group received 12 g of vitamin C/50 ml every 12 hours for 7 days at a rate of 12 ml/hour, and the placebo group received bacteriostatic water for injection in the same way. The primary outcome was invasive mechanical ventilation-free days in 28 days(IMVFD28). Secondary outcomes were 28-day mortality, organ failure, and inflammation progression.

**Results:** Only fifty-six critical COVID-19 patients were ultimately recruited due to the early control of the outbreak. There was no difference in IMVFD28 between two groups. During the 7-day treatment period, patients in the HDIVC group had a steady rise in the  $\text{PaO}_2/\text{FiO}_2$  (day 7: 229 vs. 151 mmHg, 95% CI 33 to 122,  $P=0.01$ ). Patients with SOFA scores  $\geq 3$  in the HDIVC group exhibited a trend of reduction in 28-day mortality ( $P=0.06$ ) in univariate survival analysis. IL-6 in the HDIVC group was lower than that in the placebo group (19.42 vs. 158.00; 95% CI -301.72 to -29.79;  $P=0.04$ ) on day 7.

**Conclusion:** This pilot trial showed that HDIVC might show a potential signal of benefit for critically ill patients with COVID-19, improving oxygenation even though it failed to improve IMVFD28.

**Clinicaltrial.gov identifier and date:** NCT04264533. Registered February 14 2020.

## Introduction

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection has become a global health issue, with more than 400,000 deaths worldwide [1, 2]. While the majority of patients presented with mild symptoms and did not even need hospitalization[3], nearly 30% of adult patients suffer from severe pneumonia and acute respiratory distress syndrome (ARDS), often associated with sepsis or septic shock, and multiple organ (kidney, liver, and heart) failure. Patients with ARDS and systemic complications require critical care and[4] complicate with a higher risk of death (28%)[5, 6] Due to the lack of effective medications against SARS-COV-2, the main management is supportive therapy.

Similar to the pathophysiology of severe acute respiratory syndrome (SARS) related ARDS, SARS-CoV-2 infection stimulates the innate immune system, causing numerous types of cytokine release, namely, a “cytokine storm”, inducing systemic inflammatory response[7, 8] and multiple organ failure[9, 10]. A retrospective study on SARS suggested that the worsening after 2 weeks was not related to uncontrolled viral replication but related to immunopathological damage[11]. Therefore, antiviral therapy alone may be insufficient to treat COVID-19 patients.

Vitamin C (ascorbic acid, ascorbate) functions as a potent water-soluble antioxidant by directly scavenging oxygen free radicals and acting as an essential co-factor for the production of catecholamines, vasopressin, and cortisol in the human body[12]. Vitamin C is also found in high concentrations in leukocytes and implicated in several immune responses and functions[13]. Emerging evidence in preclinical studies indicated that vitamin C played a crucial role in ameliorating the effects of inflammation by inhibiting proinflammatory cytokine production, assisting immunoregulation, neutralizing reactive oxygen species (ROS), and protecting host cells[14, 15]. Hypovitaminosis C was ubiquitous in critically ill patients, and approximately 40% of the patients had a severe deficiency[16], while the low vitamin C serum level cannot be corrected by oral supplementation due to the issue of pharmacokinetics[17]. In a latest research, of 18 adult ICU patients COVID-19 who met ARDS criteria, 94.4% had undetectable vitamin C levels and 1 patient had low levels[18]. Thus, high-dose intravenous vitamin C (HDIVC) was added to the standard therapy of critically ill patients in recent studies, such as sepsis[19-21], ARDS[21, 22], cardiac surgery[23], and burn[24]. The results showed that HDIVC was safe for critically ill patients and significantly reduced vasopressor support[25], limited organ injury[26], shortened the duration of mechanical ventilation[27] and ICU stay[28], and safety/feasibility in severe sepsis[19]. Additionally, vitamin C has direct nonspecific antiviral activity in vitro[29], although it is unclear whether this confers any protection to humans with COVID-19.

Therefore, we hypothesized that HDIVC together with conventional treatments would improve the outcomes for adult patients admitted to the ICU due to severe COVID-19 by preventing cytokine storms and reducing lung and other organ injuries. In this context, we conducted this multicenter, randomized, blind clinical trial to provide a therapeutic strategy for critically ill patients with COVID-19.

## Methods

This study is a multicenter, randomized trial that was approved by the ethics committee of Zhongnan Hospital of Wuhan University (#2020001). This study was conducted in the ICUs of Zhongnan Hospital of Wuhan University, Leishenshan (Thunder God Mountain) Hospital, and Taihe Hospital from February 14, 2020, to March 29, 2020. The ICUs specifically for COVID-19 from Zhongnan Hospital and Leishenshan Hospital were managed by the same team. The trial was registered on the website of ClinicalTrials.gov (ID: NCT04264533; registered February 14 2020) before patient recruitment.

### Patient enrollment

Patients were screened and enrolled following admission to the three ICUs. The patients who were diagnosed as severe SARS-CoV-2 related pneumonia, appeared or had a high risk of multiple organs injury would be transferred to ICU. The following inclusion criteria were met: (1) age  $\geq 18$  and  $< 80$  years; (2) RT-PCR positive for SARS-CoV-2; (3) pneumonia confirmed by chest imaging; and admission to the ICU. Exclusion criteria were  $\text{PaO}_2/\text{FiO}_2(\text{P/F}) > 300$  mmHg, allergy to vitamin C, pregnancy or breastfeeding, expected survival duration  $< 24$  hours, and previous history of glucose-6-phosphate dehydrogenase deficiency or end-stage pulmonary disease. Patients who were already enrolled in other clinical trials were

excluded as well. If these criteria were met within 48 hours of ICU admission, informed consent was obtained from the patients or their family members. When the patients' actual treatment time was less than 3 days due to death or discharge from the ICU, they were removed from this trial. The reason was because the efficacies of the treatments could not be evaluated with limited times of treatment.

### **Randomization, allocation and blinding**

Each ICU was assigned with an independent random numeric table generated by Microsoft Excel 2019 by the primary investigator alone. Each table had equal numbers of 1 and 2, which represented the placebo group (bacteriostatic water infusion) and treatment group (HDIVC), respectively. The generated random list was stored by the principal investigator who was not involved in the treatment of patients and hidden to the other investigators. When a patient was transferred to the ICU and met the enrolment criteria, the clinician on duty would inform the principal investigator and obtain a number from the list. Then, participants were enrolled in the corresponding group according to the chronological order of ICU recruitment. The grouping and intervention were unknown to the participants and investigators who were responsible for data collection and statistical analysis. VC injection and sterile water for injection were both colourless and contained in the same brown syringes with different marks and without explanations on the syringe to make sure that patients could not distinguish the treatment they receive.

### **Study interventions**

Patients were randomized to receive vitamin C or placebo within 48 hours after admission to the ICU. To control the infusion rates accurately and not affect the fluid management of severe patients, we infused vitamin C or placebo via central vein catheterization controlled by a pump. The study groups in this trial were 1) HDIVC: 24 g vitamin C per day. Patients were infused with 12 g vitamin C diluted in 50 ml of bacteriostatic water every 12 hours at a rate of 12 ml/hour by infusion pump for 7 days. 2) Placebo: 50 ml of bacteriostatic water infused every 12 hours at the same rate. Study interventions were initiated on the same day as informed consent and randomization. The preparation, transportation, storage, and use of therapies (VC and bacteriostatic water for injection) were in line with the drug management protocol in each hospital.

#### **General treatments and standard procedure of ventilation supports**

In addition, other general treatments followed the latest COVID-19 guidelines[30]. **Oseltamivir and azithromycin** were usually used in the general ward. After ICU admission, low weight molecular heparin was applied for the prevention deep vein thrombus. Piperacillin/tazobactam was used for patients receiving tracheal intubation.

If the patients showed the symptoms of rapid deterioration of hypoxemia, severe ARDS, or septic shock, hydrocortisone(1mg/kg/day) could be considered.

Respiratory support (IMV, NIV and HFNC) were given to patients with hypoxic respiratory failure and ARDS. If respiratory failure could not be improved or worsened continuously within a short time after

using HFNC or NIV, intubation were performed and the approach of lung-protective ventilation was applied. ECMO was considered as the rescue therapy when the refractory hypoxemia was difficult to be corrected by protective lung ventilation [4]. When patients' respiratory functions improved and were ready for weaning from the ventilators, the spontaneous breathing test (SBT) was performed. After the SBT was passed, invasive ventilator was considered to remove with the endotracheal tube extubation.

## Risks and Adverse Events

Adverse events(AEs) related to HDIVC included (1) nausea or vomiting during or after infusion of VC; (2) electrolyte disturbance; and (3) acute kidney injury, as described by Khoshnam-Rad [31]. AEs and serious adverse events (SAEs) were observed and followed in accordance with the good clinical practice guidelines issued by the National Medical Products Administration of the People's Republic of China. If any severe adverse events were observed during infusion, the infusion was stopped immediately, and the patient's vital signs were carefully monitored. All the AEs and SAEs were recorded in details, and the causal relationship between the infusion and AEs was analyzed.

## Data collection and management

Baseline data, which included demographics, anthropometrics, comorbid conditions, vital signs, Acute Physiology and Chronic Health Evaluation II (APACHE II) scores, and Glasgow coma scale (GCS) scores, were obtained on the day of randomization. Laboratory data, sequential organ failure assessment (SOFA) scores,  $\text{PaO}_2/\text{FiO}_2$ , and other treatments used were monitored on days 1, 3, and 7 (day 1 was defined as the day of the first administration of vitamin C).

The primary outcome of the study was invasive mechanical ventilation (IMV)-free days in 28 days (IMVFD28). Secondary outcomes included 28-day mortality, organ functions and inflammatory parameters, including white blood cell counts, neutrophil counts, lymphocyte counts, procalcitonin, interleukin-6 (IL-6), and C-reactive protein (CRP). Multi-organ dysfunction was assessed using SOFA scores. Additionally, vasopressor days, respiratory support days (including invasive and non invasive mechanical ventilation), IMVFD28, patient condition improvement rate, patient condition deterioration rate, length of ICU and hospital stay, ICU and in-hospital mortality were recorded as additional secondary outcomes of this research. IMVFD28s were defined as the number of days a patient was extubated after recruitment to day 28. If the patient died with MV, a value of zero was assigned. Deterioration of the patient's condition was defined as the patient requiring HFNC or NIV on day 1 and requiring ECMO or IMV, or dying, after 7 days of treatment. Improvement of the patient's condition was defined as the patient requiring ECMO or IMV on day 1 and switching to HFNC, NIV, or discharged from the ICU after 7 days of treatment. The P/F was calculated based on the  $\text{PaO}_2/\text{FiO}_2$ , and we choose the lowest values recorded on the specific day. All the data were collected from the clinical information system of three ICUs. Septic shock was identified according to International Guidelines for Management of Sepsis and Septic Shock(2016). Acute kidney injury was identified according to the Kidney Disease: Improving Global Outcomes definition. Acute cardiac injury was defined as the serum levels of troponin I were above the

99th percentile upper reference limit or new abnormalities were shown in electrocardiography and echocardiography. Acute liver failure (ALF), which is defined as coagulopathy (INR  $\geq 1.5$ ), hepatic encephalopathy, and onset less than 26 weeks in a patient without underlying chronic liver disease. Coagulation disorders was defined as the presence of D-dimer  $>0.24\text{mg/L}$  or FDP  $> 5\text{mg/L}$ .

## Statistical analysis

The sample size was calculated according to primary endpoint, As this trial began at the early stage of COVID-19, such preliminary data lacked, and the sample size was finally calculated from the pervious studies on ARDS. We used the non-inferiority test formula to calculate the sample size with a one-sided error rate ( $\alpha$ ) of 2.5%, a power of 80%, and a withdrawal rate of 10%, and the anticipated sample size was 140. With the control of the epidemic, this trial was stopped early, and the number of qualifying COVID-19 patients did not satisfy the anticipated sample size. Thus, we considered this trial as the pilot trial. Numerical variables are described as the mean with standard deviation (SD) or median with interquartile range (IQR) according to distribution and were compared with the t-test/Mann-Whitney U test. Category data are represented as frequencies and proportions and compared with the chi-square test and Fisher's exact test. The primary intention-to-treat analysis included all randomised participants. For the outcome variables, the hazard ratio and 95% CI were estimated by the Cox proportional risk model for mortality, and odds ratios with 95% CI were calculated by binary logistic regression for the other variables. Kaplan-Meier analysis was used to estimate the 28-day mortality to reflect the early survival differences for the two groups, and survival curves were compared with the Wilcoxon test. Survival analyses were further performed in subgroup with SOFA score more than 3. The testing was 2-sided, and a  $P\text{-value} < 0.05$  was considered statistically significant. SPSS 20.0 and GraphPad Prism 8.0 were used to complete data processing and statistical analysis.

# Results

## Baseline Characteristics of the Patients

A total of 119 patients were identified (Figure 1), 56 patients of them were enrolled and randomised in this study from February 14, 2020, to March 29, 2020. Patients were enrolled in the Leishenshan (Thunder God Mountain) Hospital (39 patients), Zhongnan Hospital of Wuhan University (11 patients), and Taihe Hospital of Hubei University of Medicine (6 patients). All participants (56) were included in the primary intention-to-treat analysis, 50 (89.2%) received the full 7-day treatment course, 4 (7.14%) only received 5 or 6 days of treatment due to discharge from the ICU, and 2 of them only received treatment for less than 3 days due to early death of natural process. Table 1 shows the baseline demographic and clinical characteristics of the 56 patients.

The average age of the study patients was  $66.7 \pm 12.7$  years, and 66.1% of the patients were male. The APACHE II score of all patients was 13.5 (IQR, 10.2- 15.7), with no differences between groups. The most common comorbidity was hypertension (44%), followed by diabetes (30%) and coronary heart disease (22%). The average time from symptom onset to starting HDIVC treatment was 17 (11-25) days. No

significant differences in vital signs, laboratory results, disease severity, or treatments were observed between groups at baseline.

## Primary Outcome

The IMVFD28 was 26.0 days[9.0-28.0]in HDIVC, and 22.0 days[8.50-28.0] in placebo group, but this difference was not statistically significant (  $P=0.57$ , HR, CI:4.8[-4.7 to 7.2]) (Figure 2).

## Secondary Outcomes

Kaplan-Meier analysis was used to estimate the 28-day mortality, and survival curves were compared with the Wilcoxon test ( $P=0.27$ ) among patients with COVID-19. Cox regression was used for multiple comparisons ( $P=0.31$ , HR, 0.50 [95% CI 0.2 to 1.8]). (Figure 3). HDIVC infusion exhibited a trend of reduction in 28-day mortality ( $P=0.06$ ) in more severe patients (SOFA score  $\geq 3$ ) using univariate survival analysis, and Cox regression showed a similar results ( $P=0.07$ , HR, 0.32 [95% CI 0.10-1.06]).

As shown in Figure 4, the median SOFA score increased from 2.00 to 6.00 in the placebo group while it slightly decreased from 3.50 to 3.00 in the HDIVC group on day 7. However, there was no statistically significant difference in SOFA scores between the two groups on days 3 and 7. During the 7-day treatment period, the P/F in the HDIVC group was 228.52 mmHg, and 150.70 mmHg in the control group ( 95% CI 33.17 to 122.47;  $P=0.01$ ), and improved over time in HDIVC group (Figure 4). The delta P/F from day 1 to day 7 was ( $20.0 \pm 96.68$  in HDVIC and.  $-51.88 \pm 150.72$  in control,  $P=0.04$  (difference 41.02(5.92-172.45)). IL-6 in the HDIVC group dropped to 9.42 pg/ml , while it it increased to 158.00 pg/ml in the placebo group (95% CI -301.72, -29.79;  $P=0.04$ ) on day 7. There was no significant difference in other anticipated infectious indicators and inflammation biomarkers between the two groups (Table 3). In addition, total bilirubin was 8.40 in HDIVC group, and 14.85 in placebo group(95% CI -18.33 to -0.59;  $P=0.03$ , Table 3). The ICU mortality of severe patients (baseline SOFA score  $\geq 3$ ,  $n=42$ ) was improved in the HDIVC group ( $P=0.03$ , HR, 0.22 [95% CI 0.06-0.90]).

## The differences of other treatments

Table 1 demonstrates the differences in other treatments between the two groups. There were no significant differences in corticosteroids, antiviral agents or antibiotics.

## Adverse Events

During the 7-day infusion period, serum creatinine was 64.20[46.58-85.45] on day 1 and 57.50[39.95-71 ] umol/L on day 7 in HDIVC, versus 64.20[52.00 -81.70] on day 1 and 63.50[51.70-104.50] umol/L on day 7 in control group. Similarly, there were no changes in total bilirubin from day 1 to day 7 in HDIVC, while there were a slight increase from day 1 to day 7 in placebo. No other study-related adverse events were found, and no patients hadn't finished the study due to SAEs.

## Discussion

This pilot trial shows that the addition of high-dose (24 g per day for 7 days) intravenous vitamin C to the standard-of-care treatment for severe COVID-19 may provide a potential signal of benefit. To our understanding, it was the first trial on a high dose of vitamin C infusion in patients with severe COVID-19.

Other previous studies suggested a protective role of vitamin C infusion in acute lung injury (ALI) and ARDS [21]. Moreover, the latest meta-analysis from eight vitamin C trials of a total of 685 patients indicated that vitamin C shortened the duration of mechanical ventilation in critically ill patients[27]. SARS-CoV-2 primarily affects the lung and causes pneumonia. Respiratory failure from ARDS is the leading cause of mortality from COVID-19[32]. Similar to sepsis-induced ALI/ARDS, the rapid increase in cytokines in COVID-19 causes neutrophil sequestration in the lung, which damages the alveolar capillaries[9, 10]. In sepsis modeling of mice, parenterally infused VC demonstrated a protective effect on the lung [33, 34]. The potential mechanisms included limiting cytokine surges, improving alveolar fluid clearance, preventing vascular injury, restoring endothelial and alveolar epithelial integrity, and augmenting lung barrier cell function. In our study, the P/F increased rapidly after the initiation of HDIVC, which was likely the result of pulmonary ventilation function improvement, based on the above mechanisms.

Previous clinical trials showed that HDIVC may reduce the extent of multiple organ failure and may improve the short-term outcomes of sepsis[19,21]. Additionally, plasma ascorbic acid levels were inversely correlated with the incidence of multiple organ failure and the risk of mortality[35]. We suspected that patients with worse organ dysfunction may have a more severe vitamin C deficiency, while high-dose intravenous VC effectively improved the deficiency and subsequently improved organ function [16]. Thus, the benefit was more significant in more severe COVID-19 patients with a higher baseline SOFA score in our study.

In this study we chose 24 g of vitamin C infusion for seven days. The main reason was based on two aspects: the efficacy and safety. The metabolism of Vitamin C (VC) in the blood is very fast, only large dose and long course of VC supplement can maintain an adequate concentration in blood. In previous study [19], 50 or 200mg/kg/day (equivalent to 12 g/day) in 4 days VC treatment showed a signal of benefit in sepsis or ARDS patients, but not a desired efficacy. Thus, we tried to improve the efficacy by increasing the dosage and course in this trial. Actually, the 24g dose is far less than the conventional IVC dose for cancer patients. In addition, high-dose VC has been clinically used for several decades and a recent NIH expert panel document states clearly that this regimen (1.5 g/kg body weight) is safe and without major adverse events (<https://www.cancer.gov/about-cancer/treatment/cam/hp/vitamin-c-pdq>). Therefore, we believe that this 24g/day for 7 days is safe and more effective.

In addition, high levels of IL-6 were observed in patients with COVID-19 and might serve as a predictive biomarker for disease severity[5, 36, 37]. Mechanistically, IL-6 acts as a critical cytokine in the systemic inflammatory response [38], leading to a myriad of biological effects that contribute to pulmonary infiltration and organ damage[39, 40]. In a recent trial, tocilizumab[41], a recombinant humanized anti-

human IL-6 receptor antibody, improved clinical symptoms by attenuating inflammation in COVID-19. The findings of the decline in IL-6 in our cohort were consistent with basic research showing that vitamin C inhibited the production and release of proinflammatory cytokines from human monocytes (IL-1, IL-2, IL-6, and TNF- $\alpha$ )[42]. Previous animal studies on SARS-CoV also demonstrated that inhibiting NF- $\kappa$ B, together with reduced IL-6 levels, could increase the survival rate in infected animals[37].

This study has several limitations. First, the study was started in the second half of the outbreak, and the number of qualifying COVID-19 patients decreased with the control of the epidemic so that we had to stop our trial before reaching the predefined sample size. Secondly, the initiation of vitamin C occurred more than 10 days after the first symptom, which may affect the efficacy of HDIVC. However, SARS-CoV-2 infection was characterized by mild symptoms initially, followed one week later by a rapid deterioration leading to hospitalization, and ARDS always occurred at the day 8 after the first symptom [4]. As in other trial, administration of vitamin C was initiated shortly after the onset of ARDS[21], which started a couple of days earlier than our trial. Third, the absence of data on the monitoring of serum ascorbic acid concentration and viral loading due to the potential exposure risks and limited human resources during the pandemic made it unclear whether vitamin C has direct antiviral activity against SARS-CoV-2. Fourth, we did not measure the anti-oxidative variables due to the complexity of the blood sample treatment, which was also an important feature for vitamin C. Finally, the imbalance in the patient gender distribution between the groups at baseline may have slightly influenced the outcomes.

## Conclusion

In summary, this pilot trial shows a potential signal of benefit for critically ill patients with COVID-19, with an improvement in P/F ratio even though the primary endpoint, IMVFD28, was not met. . Nevertheless, further large scale RCTs are still needed to confirm our understanding of the effect of HDIVC therapy in critically ill patients with COVID-19.

## Declarations

### Ethics approval and consent to participate

This study is a multi-center, randomized trial, which was approved by the ethic committee of Zhongnan Hospital of Wuhan University (#2020001).It was registered on the website of ClinicalTrials.gov (ID: NCT04264533) before patient recruitment. Informed consents were obtained from the patients or family members.

### Consent for publication

Not applicable.

### Availability of data and materials

The datasets used and analysed during the current study are available from the corresponding author on reasonable request.

### Competing interests

The authors declare no competing interests.

### Funding

This work was funded by the Science and Technology Department of Hubei Province (2020FCA024, 2020FCA020), and the Fundamental Research Funds for the Central Universities (2042020kfxg18, 2042020kfxg13).

### Authors' contributions

Concept and design: Zhang, Rao, Li.

Acquisition, analysis, or interpretation of data: Zhang, Rao, Li, Xiang, Guo, Luo, Meng.

Drafting of the manuscript: Zhang, Rao, Li, Backer, Peng.

Critical revision of the manuscript for important intellectual content: Zhang, Xiang, Backer, Peng.

Statistical analysis: Zhang, Zhu, Liu.

Obtained funding: Xiang, Peng.

Administrative, technical, or material support: Xiang, Rao, Peng.

Supervision: Xiang, Backer, Peng.

### Acknowledgements

Zhang, Xiang, and Peng had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. Zhang, Rao and Li contributed equally and share first authorship. Xiang and Peng are the co- corresponding author.

Data were expressed as mean±standard deviation, as median [interquartile range], or as numbers (percentage). Hazard ratio and 95% CI were estimated by Cox proportional risk model. Odd ratio with 95% CI were calculated by binary logistic regression for the rest. Absolute difference was expressed as a percentage with the 95% CI range. P values were calculated by logistic regression.  $\Delta$ 7 means the difference between the value from Day1 to Day7.

Abbreviations: IMVFD28—invasive mechanical ventilation-free days in 28 days—HDIVC: high dose intravenous vitamin C; COVID-19, coronavirus disease 2019; SD, standard deviation; IQR, interquartile range; HR, hazard ratio; OR, odd ratio; CI, confidence interval; SOFA: sequential organ failure assessment; P/F, PaO<sub>2</sub>/FiO<sub>2</sub>; CRRT, continuous renal replacement therapy; ECMO, extracorporeal membrane oxygenation; HFNC, high flow nasal cannula; IV, invasive ventilation; IMV, invasive mechanical ventilation; NIV, noninvasive mechanical ventilation; ICU, intensive care unit.

Data were expressed as mean±standard deviation, as median [interquartile range]. Odd ratio with 95% CI were calculated by binary logistic regression for the rest. P values were calculated by logistic regression.

Abbreviations: SD, standard deviation; IQR, interquartile range; HR, hazard ratio; OR, odd ratio; CI, confidence interval; HDIVC: high dose intravenous vitamin C; COVID-19, coronavirus disease 2019; SD, standard deviation; IQR, interquartile range; PCT, procalcitonin; CRP, C-reactive protein; BUN, blood ureanitrogen; PT, prothrombin time, IL-6, interleukin-6.

## Figures

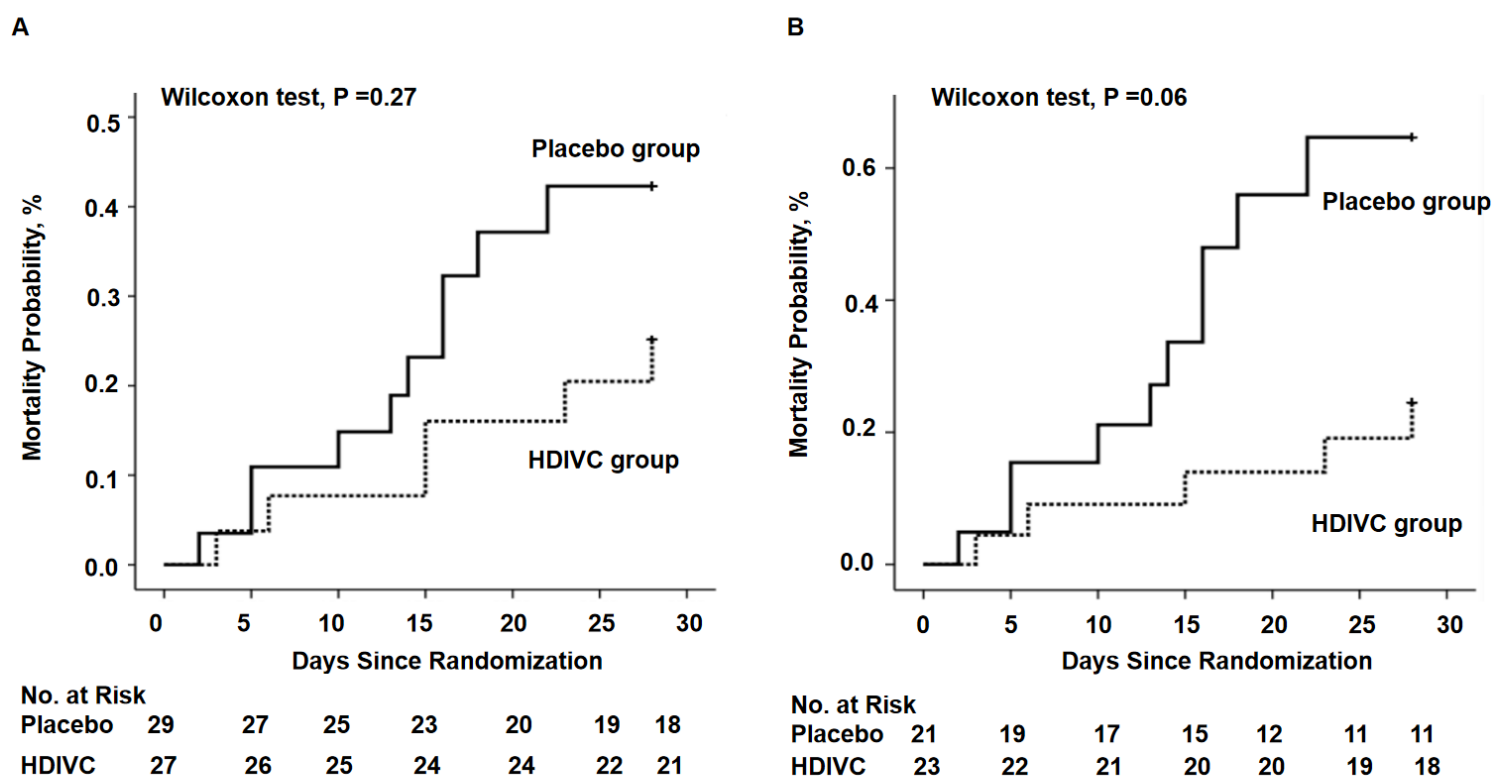

**Figure 1**

Flow chart of patients. Abbreviations: HDIVC: high-dose intravenous vitamin C.

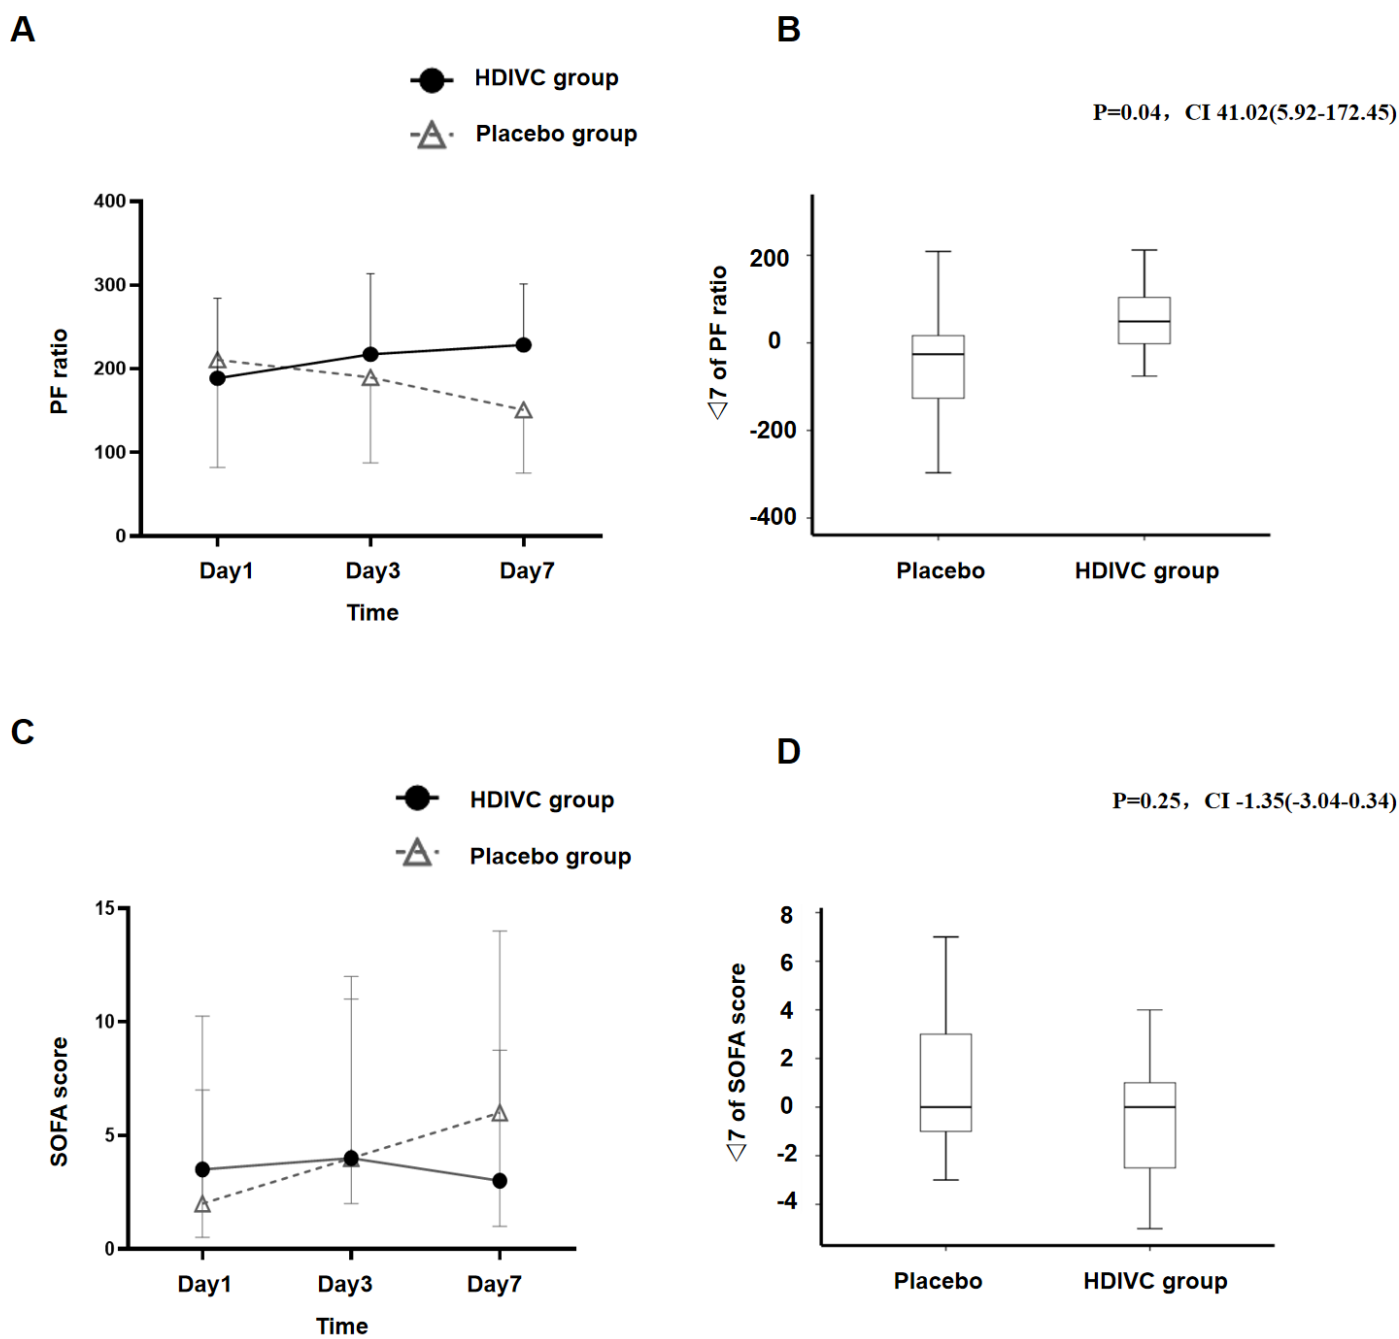

**Figure 2**

The IMVFD28 in high-dose intravenous vitamin C and Placebo group. The IMVFD28 was 26.0 days[9.0-28.0] in HDIVC, and 22.0 days[8.5-28.0] in placebo group, but this difference was not statistically significant (  $P=0.57$  CI:4.8[-4.7 to 7.2]). Abbreviations: IMV: invasive mechanical ventilation; HDIVC: high-dose intravenous vitamin C.

**Figure 3**

The 28-day mortality from randomization (day 1) to day 28. A Kaplan-Meier analysis was used to estimate the 28-day mortality, and survival curves were compared with the Wilcoxon test ( $P=0.27$ ) among patients with COVID-19. Cox regression was used for multiple comparisons ( $P=0.31$ , HR, 0.50 [95% CI 0.2 to 1.8]). B Kaplan-Meier analysis was used to estimate the 28-day mortality and survival curves were compared with the Wilcoxon test ( $P=0.06$ ) among severe COVID-19 patients (baseline SOFA score  $\geq 3$ ). Cox regression was used as multiple comparisons ( $P=0.07$ , HR, 0.32 [95% CI 0.10-1.06]). Abbreviations: HDIVC: high dose intravenous vitamin C; COVID-19, coronavirus disease 2019; SOFA: sequential organ failure assessment.

**Figure 4**

P/F and SOFA scores following high-dose intravenous vitamin C treatment. A The bars show the standard deviation (SD) of the mean. The P/F in both groups was approximately 200 at enrollment. After initiation of treatment, there was a steady rise in the P/F in the HDIVC group and a decline in the P/F in the placebo group (day 3: 217 vs. 189, 95% CI -34 to 90, P=0.37; day 7: 229 vs. 151, 95% CI 33 to 122, P=0.01). B  $\Delta$ 7 of P/F means the difference between the value from Day1 to Day7. Boxes represent the median and interquartile range (25th and 75th percentiles), and whiskers represent the range of values. The delta P/F

ratio showed a different result in two groups ( $20.0 \pm 96.68$  vs.  $-51.88 \pm 150.72$ ,  $P=0.04$ ,  $41.02(5.92-172.45)$ ).  $\Delta 7$  was calculated by the difference between the value from Day1 to Day7. C The bars showed the interquartile range (IQR) of the median. There was no difference in the initial Sequential Organ Failure Assessment (SOFA) scores of the 2 groups at baseline (vitamin C vs placebo, median,  $3.5[3.0-6.8]$  vs  $2.0[3.0-5.0]$ ). After 7-day treatment, the median of SOFA score increased from 2.0 to 6.0 in the placebo group and slightly decreased from 3.5 to 3.0 in the HDIVC group, but there were no difference between the 2 groups. D  $\Delta 7$  of SOFA scores means the difference between the value from Day1 to Day7. Boxes represent the median and interquartile range (25th and 75th percentiles), and whiskers represent the range of values. The delta SOFA scores showed no significant difference in two groups ( $0.0[-2.75- 1.0]$  vs.  $0.0[-1.0- 3.5]$ ,  $P=0.25$ , CI  $-1.35(-3.04- 0.34)$ ).  $\Delta 7$  was calculated by the difference between the value from Day1 to Day7. Abbreviations: HDIVC: SOFA, sequential organ failure assessment; P/F,  $PaO_2/FiO_2$ ; high dose intravenous vitamin C; COVID-19, coronavirus disease 2019.
