## **Abstract**

Organic-inorganic hybrid perovskite is the most promising active layer for new generation of solar cells. Despite of highly efficient perovskite active layer conventionally fabricated by spin coating methods, the need for using toxic solvents like dimethylformamide (DMF) required for dissolving low soluble metal precursors as well as the difficulties for upscaling the process have restricted their practical development. To deal with these shortcomings, in this work, lead sulphide as the lead metal precursor was produced by aqueous chemical bath deposition. PbS films were subsequently chemically converted to  $\text{PbI}_2$  and finally to mixed-cation mixed halide perovskite films. The microstructural, optical and solar cell performance of mixed cation mixed halide perovskite films were exploited. Results show that controlling the morphology of  $\text{PbI}_2$  platelets achieved from PbS precursor films enabled efficient conversion to perovskite. Using this processing technique, smooth and pin hole-free perovskite films having columnar grains of about 800 nm and a bandgap of 1.55 eV were produced. The solar cell performance consisting of such perovskite layers gave rise to a notable power conversion efficiency of 11.35% under standard solar conditions. The proposed processing technique is a very promising environmentally friendly method for the production of large-scale high efficient perovskite solar cells.

## Introduction

Organolead halide perovskites with  $ABX_3$  formula (A: methylammonium (MA), formamidinium (FA); B: Pb, Sn, etc.; X:  $Cl^-$ ,  $I^-$ ,  $Br^-$ )<sup>1</sup> are of great interest for solar cell applications owing to their remarkable properties, such as high absorption coefficient<sup>2</sup>, weak electron-hole binding energy<sup>3,4</sup>, adjustable and direct band gap<sup>5</sup> and long charge carrier diffusion length<sup>6</sup> and also facile cost-effective fabrication methods. The phenomenal performances of these alluring absorbing layers have skyrocketed their power conversion efficiencies (PCEs) from 3.8%<sup>7</sup> to over 25.2%<sup>8</sup> in a short period of ten years for perovskite solar cell (PSC) devices.

Two main routes widely used for synthesizing organometal halide perovskites are single step and sequential deposition methods. For the former one, a solution including both perovskite precursors ( $PbX_2$  (X: I, Cl, Br) and MAX ( $MA^+ = (CH_3NH_3)^+$ ) or FAX ( $FA^+ = (CH(NH_2)_2)^+$ ) is deposited via methods like spin coating<sup>9</sup>, spray deposition<sup>10</sup>, blade coating<sup>11</sup>, inkjet printing<sup>12</sup> and slot die coating<sup>13</sup> onto a substrate to form the perovskite material. Indeed, the uncontrollable precipitation of the perovskite by a single-step method often results in low reproducibility, morphological variations and a wide spread of photovoltaic performance of the devices<sup>14</sup>. To address these problems, the sequential deposition method was introduced with  $PbI_2$  layer being deposited from either a solution<sup>14</sup> phase or a vapor<sup>15</sup> phase onto substrate firstly and following conversion into perovskite by exposing to a MAX ( $MA^+ = (CH_3NH_3)^+$ ) or FAX ( $FA^+ = (CH(NH_2)_2)^+$ ) solution or vapor, which better controls the perovskite morphology and its stoichiometry and crystallinity. Therefore, the possibility of photovoltaic enhancement has been shown to be higher with this method<sup>14</sup> and is anticipated that new routes with further modifications will be required to ever enhance the solar cell performance in this way. For instance, the poor solubility of  $PbI_2$  and utilization of toxic solvents like dimethylformamide (DMF) makes the first step of the sequential deposition method, i.e., depositing  $PbI_2$  layer, not well recommended and suitable for upscaling for mass production. One approach for dealing with this problem is to use water-based metal precursor compounds.

There has been a recent trend with respect to the development of such two- or multi-step processing routes for the production of the metal halide perovskite films and solar cells from water-based metal precursors. The general procedure employed is to firstly deposit metal (M) precursor film followed by iodination leading to  $MI_2$ . This finally is chemically converted to MAX perovskite films. In addition, direct conversion of metal precursor to final perovskite has also been reported. A few metal precursors such as  $Pb^{16}$ ,  $PbO^{17,18}$ ,  $PbO_2^{19,20}$ ,  $Pb(NO_3)_2^{21-24}$ ,  $PbSe^{25}$  and  $PbS^{26-29}$ , have been developed via different deposition approaches including chemical, physical and electrochemical methods. **Table S1** summarizes different metal precursors, their processing towards the fabrication of PSC and highest PCE of the cell reported.

Lead sulphide ( $PbS$ ) is a non-halide compound with a lower bond dissociation energy (3.3 eV) compared to oxide precursors<sup>30</sup> and therefore more chemically reactive which facilitates its subsequent reduction to final perovskite films.  $PbS$  can be deposited by various techniques such as vacuum evaporation<sup>31</sup>, spray pyrolysis<sup>32</sup>, successive ionic layer adsorption and reaction<sup>33</sup>, electrodeposition<sup>34</sup>, molecular beam epitaxy<sup>35</sup>, and chemical bath deposition (CBD)<sup>36,37</sup>.

In addition to methods already developed for depositing  $PbS$ , some of them have been employed in combination with solution processing to produce final lead halide perovskite film and PSCs. Sutherland et al.<sup>26</sup> have reported atomic layer deposition of lead sulphide ( $PbS$ ) layer for the first time. The deposit was in the form of 75 nm thin film and introduced as a precursor material to be converted into the final perovskite layer<sup>26</sup>. Successive exposure to iodine vapor and methylammonium bromide was used to directly converting of two-dimensional (2D)  $PbS$  nanocrystals into nanocrystals of hybrid perovskite maintaining 2D morphology<sup>38</sup>. Radio-frequency sputtering assisted solution process has also been employed for depositing  $PbS$  films which were converted into the perovskite layer by exposing in an iodine atmosphere at room temperature, followed by immersing in a methylammonium iodide solution to be transformed to the perovskite layer<sup>27</sup>. CBD technique combined with chemical vapor deposition (CVD) has been proved to be applicable for synthesizing lead halide perovskite films whose power conversion efficiency has been reported 4.68% in a PSC<sup>28</sup>. We have recently demonstrated that lead halide perovskite films and cells were successfully fabricated based on electrodeposited  $PbS^{29}$  with a champion efficiency of

7.72%. The proposed work of electrodeposition of PbS and subsequent solution based processing towards fabrication of lead halide perovskite films provided complex interfacial electrode reactions and nucleation and growth with cuboidal grain morphology with uneven interlayer junctions which delays the charge carrier transportation and increases the recombination rates before hitting the hole transport layer.

CBD has been established as a distinct method of depositing PbS with controllable morphology along with its scalability, simplicity, low-cost and low temperature<sup>39-41</sup>. As explained above there is only one report of using CBD for depositing precursor of lead sulphide, which is combined with CVD method for final conversion to lead halide perovskite.

In most of reports related to using an alternative precursor material, the final product is MAPbI<sub>3</sub>. FAPbI<sub>3</sub> is known with its broader absorption spectrum and narrower bandgap material than MAPbI<sub>3</sub>, however, its morphology and phase structure have significant effects on its performance in perovskite solar cells. In most cases, the PCE of FAPbI<sub>3</sub> based inverted planar devices are lower than those of MAPbI<sub>3</sub> because of the inferior morphology of FAPbI<sub>3</sub> film. It is well known that the performance of devices based on MAPbI<sub>3</sub> would degrade greatly in high temperature or high humidity level. FAPbI<sub>3</sub> is more stable than MAPbI<sub>3</sub>, but it has an undesirable phase transition between  $\delta$ -phase (yellow phase-more stable) and perovskite  $\alpha$ -phase (black phase) at different temperatures<sup>42</sup>. Adding small amount of MA<sup>+</sup> induces crystallization of black phase of FA-based perovskite and inhibit the phase transition<sup>43</sup>. Therefore, mixing anions and cations is an important approach to provide high performance and stable devices.

Therefore, in this work, we employed a toxic solvent-free route based on CBD to deposit PbS as the lead metal precursor film is introduced for fabricating perovskite films with the mixed cations (FA, MA) and mixed halides (I, Br, Cl). The process started with the chemical bath deposition of a PbS seeding layer. Then, PbS film was exposed to iodine vapor to chemically convert to PbI<sub>2</sub>. Depending on temperature of iodination, the morphology of PbI<sub>2</sub> layer changed. The effect of different morphologies on final step i.e. chemical conversion to perovskite film and also photovoltaic performance of achieved layers in the perovskite solar cell studied. This study represents the versatility of proposed route to produce fully covered and high quality perovskite layer. After current optimization, the power conversion efficiency

(PCE) of 11.35% was achieved under standard condition (air mass (AM) 1.5, 100 mW cm<sup>-2</sup>) with potential enhancement after several trials in future.

## Results and discussion

### *Chemical bath deposition of PbS films*

**Figure 1a** shows the XRD pattern of chemically deposited PbS layer. As is evident from the XRD pattern, PbS thin film exhibits a face-centered-cubic (fcc) microstructure. The main Bragg diffraction peaks located at 25.78°, 30.548°, 43.32° correspond to (111), (200) and (220) crystalline planes, respectively (JCPDS No.00-05-0592). Except the peaks of PbS and substrate (FTO and TiO<sub>2</sub>), no other peaks were detected which certified the purity of the deposited PbS film. The film formation in the chemical bath deposition method starts with the supersaturation of the solution which results in the production of contents of cations and anions exceeding the solubility. Taking this point into account, the formation of PbS from aforementioned chemical bath includes following steps: dissolving Pb(CH<sub>3</sub>COO)<sub>2</sub> in aqueous solution results into the formation of Pb<sup>2+</sup> ions. Dissociation of thiourea in solution leads to release of SH<sup>-</sup> ions. SH<sup>-</sup> ions go through reaction with hydroxide species to produce S<sup>2-</sup> anions. Finally, PbS thin film forms via adsorbing of Pb<sup>2+</sup> cations on substrate and combining with S<sup>2-</sup> anions. The overall growth of PbS film takes place by ion-by-ion process on the substrate. The corresponding reactions are as follows (reactions 1-4)<sup>44</sup>:

SEM micrographs taken from top (**Figure 1b**) of the chemically deposited PbS shows a compact structure which consists of smooth, uniform spherical and densely packed grains. The film well covers the substrate

completely. The thickness of PbS layers deposited for various immersion time of the substrate inside the bath, as well as the thickness of corresponding PbI<sub>2</sub> and perovskite films, was measured and summarized in **Table S2**.

**Figure 1c** represents the AFM image of the PbS thin film deposited on the mp-TiO<sub>2</sub> /bl-TiO<sub>2</sub>/ FTO substrate. It indicates that the PbS thin film is composed of particles of granular nature which are smoothly and uniformly distributed on the surface. The root-mean-square roughness (*Rq*) of film is measured about 31.3 nm. Furthermore, the particle size distribution histogram calculated on the SEM image is shown in **Figure 1d**. Accordingly, the average size of granular grains of PbS is approximately 119 nm. The formation of uniform compact grains in the microstructure of PbS films is achieved as a consequence of multiple nucleation followed by one-step growth<sup>45</sup>.

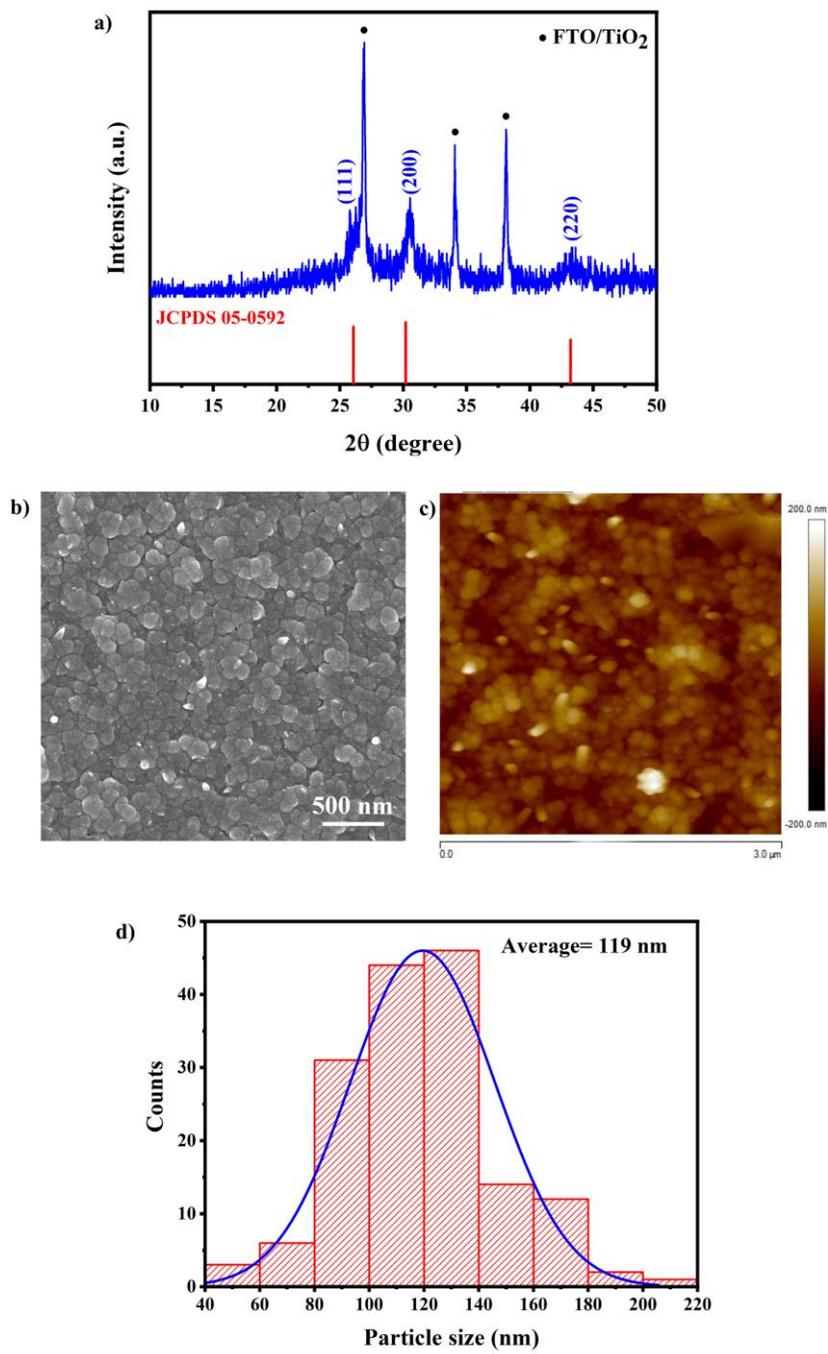

Evaluating the morphology and composition of obtained film showed that the PbS thin film deposited through dipping the substrates inside chemical bath for 60 min have low surface roughness and full coverage of electron transport layer (ETL) layer. Thus, it is a good candidate for using as a precursor layer for preparing final lead halide perovskite film.

#### *Chemical conversion of PbS to PbI<sub>2</sub> films*

The iodination of chemically deposited PbS films were carried out by putting PbS films in iodine vapor environment at two different temperatures of 120 and 155°C. From XRD patterns (**Figure 2a,b**), it is obvious that whole PbS is converted to PbI<sub>2</sub> and instead of initial PbS peaks, some new peaks can be seen which are in accordance with crystallite planes of PbI<sub>2</sub>(00-007-0235). The possible reaction can be<sup>27</sup>:

5

**Figure 1.**

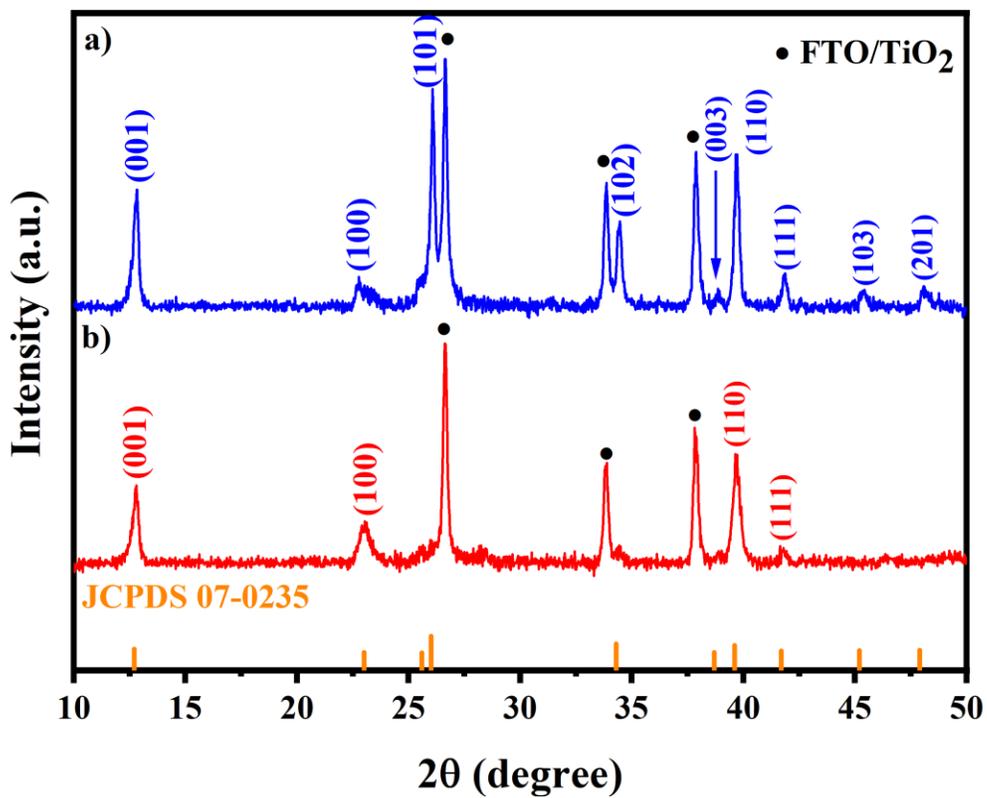

Structural and morphological characterization of chemically deposited PbS film. a) XRD diffraction pattern b) surface SEM image c) AFM image and d) grain size distribution histogram.

The position of the main Bragg diffraction peaks are the same for two  $\text{PbI}_2$  films achieved at the two temperatures. However, there are some difference in the intensity of the peaks related to  $\text{PbI}_2$  crystallite planes, depending on the temperature of the reaction. The XRD pattern of  $120^\circ\text{C}$  - $\text{PbI}_2$  represented almost all the characteristic peaks of  $\text{PbI}_2$ , including (001), (100), (101), (102), (003), (110), (111), (103) and (201) reflections. Whereas the pattern of  $155^\circ\text{C}$  - $\text{PbI}_2$  revealed four major peaks of (001), (100), (110) and (111). Analysis of the preferred orientation is performed through calculation of texture coefficients. **Table 1** shows the  $TC(hkl)$ s the observed planes. For the  $120^\circ\text{C}$  - $\text{PbI}_2$ , (001) plane has the highest  $TC(hkl)$  value. While for  $155^\circ\text{C}$  - $\text{PbI}_2$  the (100) plane is dominant. The change in crystallographic direction vs the temperature of substrate is in agreement with results observed in vapor-deposited  $\text{PbI}_2$  crystals<sup>46</sup>. Since XRD diffractometer collects reflections only from the crystallographic planes parallel to substrate, so we expect this variation can be originated from the difference in microstructure features.

**Figure 3a,b** show the SEM micrographs of  $\text{PbI}_2$  films prepared at 120 and  $155^\circ\text{C}$ , respectively.  $\text{PbI}_2$  layers fabricated by the our present method exhibit clearly grain boundaries and incompact structure, different from the  $\text{PbI}_2$  layers fabricated by conventional spin coating method which have fuzzy domain boundaries and few grain boundaries.

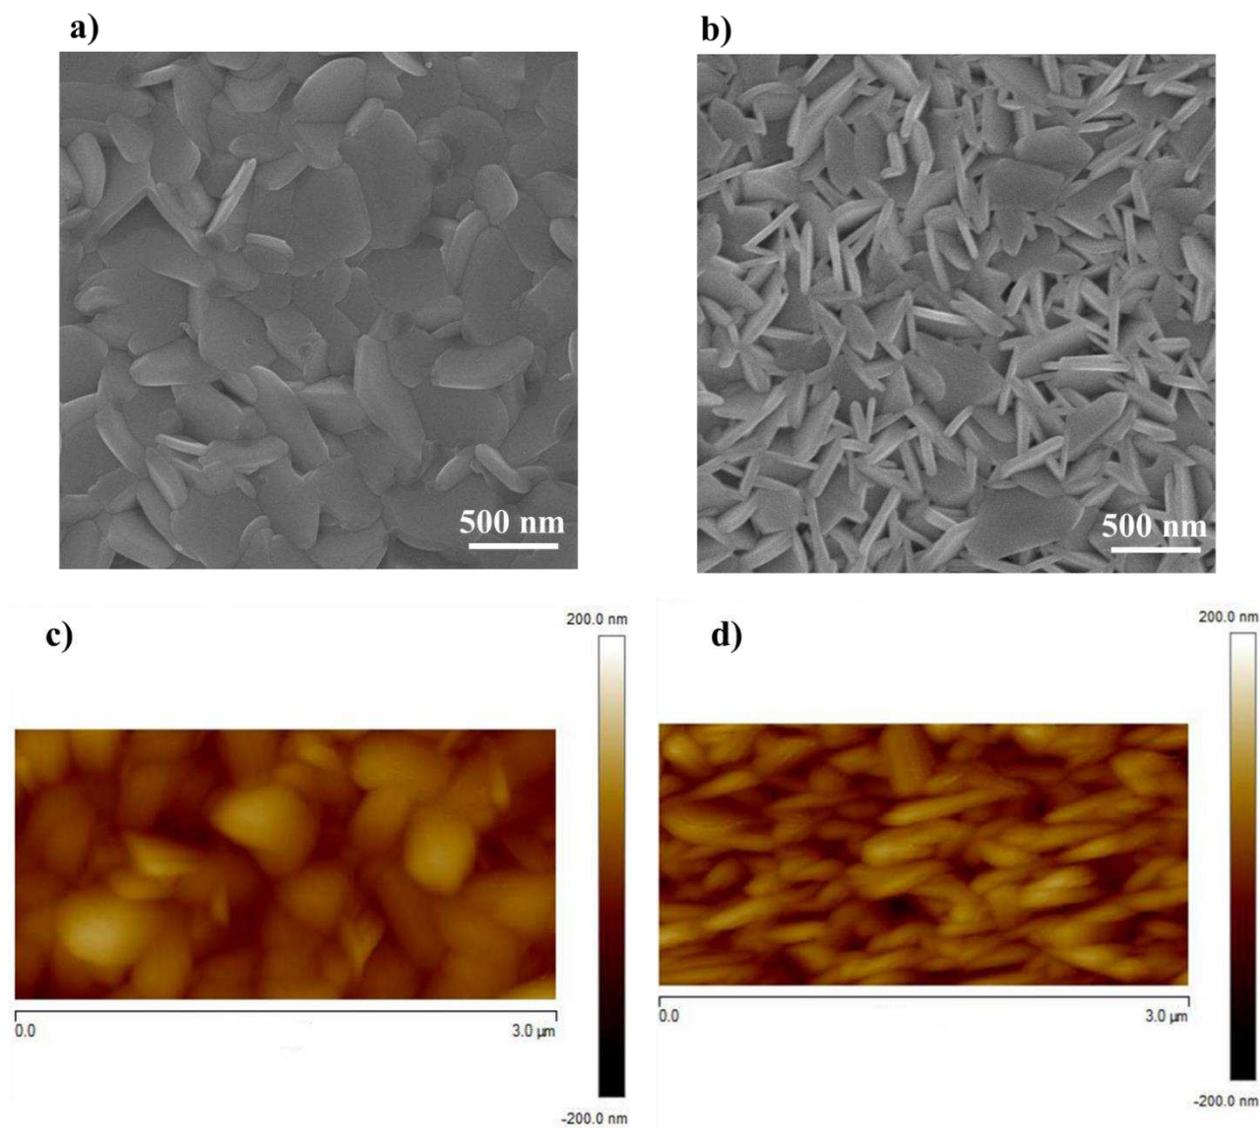

Furthermore, as expected from XRD results, there is obvious difference amongst the structure of  $\text{PbI}_2$  layers obtained at two different temperatures. As can be seen from **Figure 3a**,  $120^\circ\text{C}$  - $\text{PbI}_2$  has platelet crystals with hexagonal shape which are lying parallel to substrate. This structure is consistent with the calculated TC values. According to TC results shown in **Table 1**, for  $120^\circ\text{C}$  - $\text{PbI}_2$ , the preferred orientation is in the (001) plane that is perpendicular to c-axis in hexagonal crystal system. So, this  $\text{PbI}_2$  develops a layered structure with basal planes parallel to substrate. on the other hand, in the case of  $155^\circ\text{C}$  -  $\text{PbI}_2$ , highest TC is for (100) plane which is parallel to c-axis of hexagonal crystal. Accordingly, as can be seen from **Figure 3b**, lots of the plate-like grains are positioned perpendicular to the substrate. This special orientation causes the formation of lots of voids in-between which accounts for the observed

porous  $\text{PbI}_2$  layer. The AFM images of aforementioned  $\text{PbI}_2$  films are also taken and presented at **Figure 3c,d**, respectively. The AFM images certifies the same morphology for achieved films.

**Figure 2.**

XRD patterns of  $\text{PbI}_2$  films obtained from iodination of chemically deposited  $\text{PbS}$  films at a) 120 and b) 155°C.

**Figure 3.**

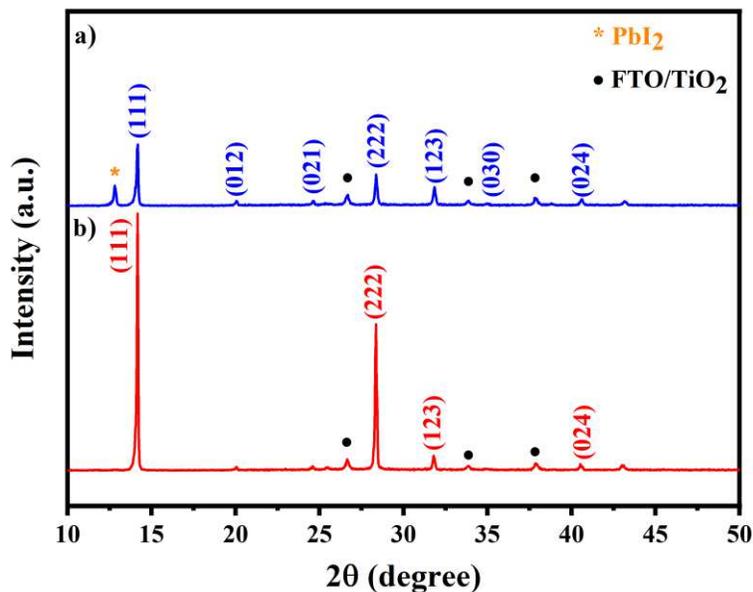

Top surface SEM images and AFM images of  $\text{PbI}_2$  films obtained from iodination of chemically deposited PbS films at a,c) 120 and b,d) 155°C.

*Production of final mixed-cation mixed halide perovskite films*

It has been well demonstrated that changing the morphology of  $\text{PbI}_2$  film will provide a chance to modify the morphology and quality of perovskite layer, which may influence the PSC device performance<sup>47</sup>. In this regard, we have investigated the effect of two different  $\text{PbI}_2$  films on the solar cell properties.

Perovskite active layers were formed by spin coating of a solution of FAI:MACl:MABr (85:10:10 mg in 1 ml IPA) on top of as-converted  $\text{PbI}_2$  layers on mp- $\text{TiO}_2/\text{bl-TiO}_2/\text{FTO}$ .

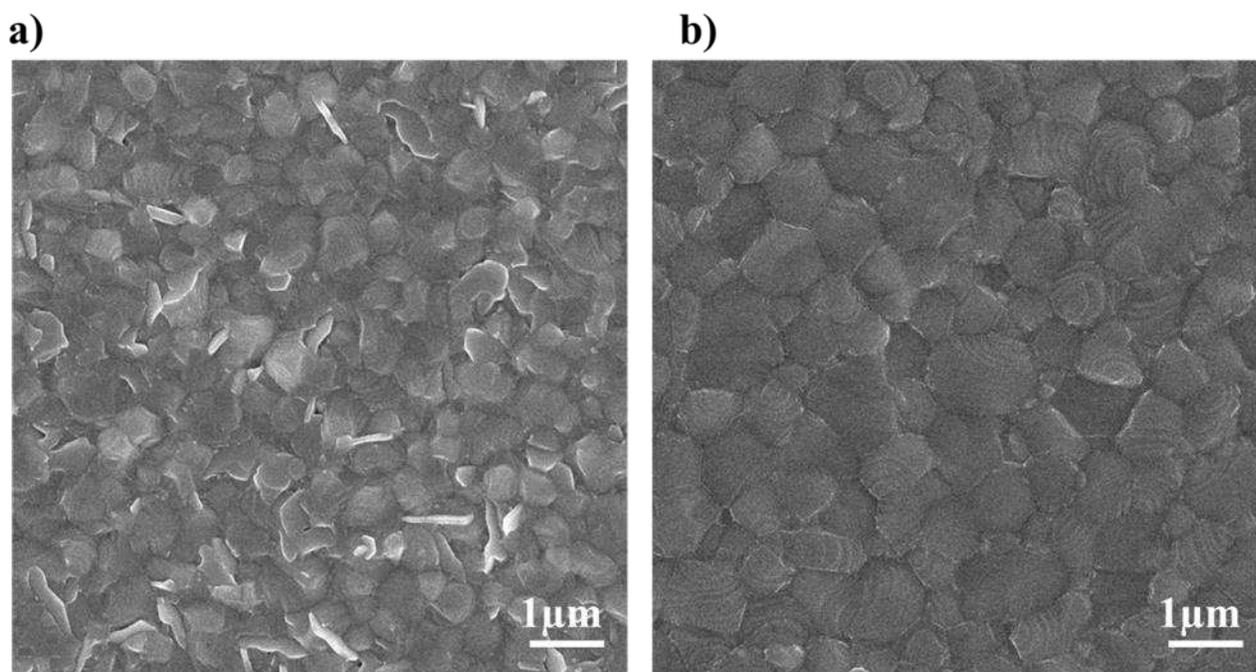

As shown in **Figure 4a,b**, the composition of the perovskite films achieved after iodination of  $120^\circ\text{C}$ - $\text{PbI}_2$  and  $155^\circ\text{C}$ - $\text{PbI}_2$  were characterized by XRD. After the third step, the presence of XRD peaks at  $2\theta = 14.16^\circ, 20.04^\circ, 24.6^\circ, 28.36^\circ, 31.8^\circ, 34.92^\circ, 40.52^\circ$  and  $43^\circ$ , corresponding to the reflections from (111), (012), (021), (222), (123), (030), (024) and (333) planes of  $\alpha$ -phase perovskite<sup>48</sup>, respectively, supports the formation of perovskite structure. Meanwhile, there is no trace of XRD peaks of  $\delta$ -phase at  $11.6^\circ$ , indicating that selected composition and method is conducive to achieve desirable  $\alpha$ -phase perovskite. For perovskite film prepared from  $120^\circ\text{C}$ - $\text{PbI}_2$  an additional peak at  $12.8^\circ$  corresponding to (001) lattice plane of  $\text{PbI}_2$  suggests the incomplete conversion to perovskite. By contrast, in the case of perovskite from  $155^\circ\text{C}$ - $\text{PbI}_2$ , the peaks of  $\text{PbI}_2$  completely disappears, indicating the complete conversion into photoactive black phase. In addition, for former perovskite all the peaks are enhanced in intensity than those of latter perovskite. It means that modifying the precursor  $\text{PbI}_2$  morphology may also increase the crystallinity of final perovskite film.

**Figure 4.**

XRD patterns of perovskite films converted from a)  $120^\circ\text{C}$ - $\text{PbI}_2$  and b)  $155^\circ\text{C}$ - $\text{PbI}_2$ .

The SEM images taken from the top surface of the final perovskite films, made from  $\text{PbI}_2$  layer converted at two temperatures of 120 and 155°C, are shown in **Figure 5a,b**, respectively. The perovskite film produced from the 120°C -  $\text{PbI}_2$  layer exhibits the existence of disconnected grains with edges which may be unconverted  $\text{PbI}_2$  since heavy-atom regions appear with brighter contrast in the SEM images<sup>49</sup>. EDX analysis of the white regions also confirms the speculated composition, (**Figure S1**). In contrast, the perovskite film produced from the 155°C - $\text{PbI}_2$  layer shows smooth and homogenous perovskite grains with sizes up to 800 nm which is comparable to that observed for perovskite films prepared by a conventional spin-coating method<sup>50</sup>. Furthermore some spiral form lines can be seen on grains. According to the theory of crystal growth, it can be the result of spiral growth mechanism which leads to a step-like morphology<sup>51</sup>.

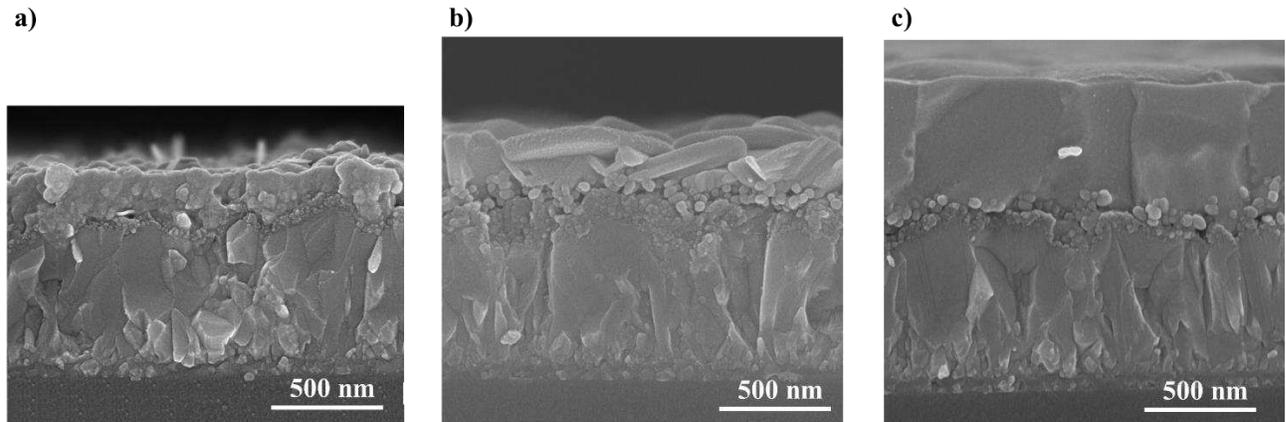

**Figure 5.**

SEM images of perovskite films converted from a) 120°C- $\text{PbI}_2$  and b) 155°C- $\text{PbI}_2$ .

According to both XRD and SEM results, it can be concluded that the reaction rate of 155°C -PbI<sub>2</sub> is faster than that of 120°C -PbI<sub>2</sub>. In the case of 155°C - PbI<sub>2</sub>, the vertically arranged nanoplates create a large degree of porosity on the surface of PbI<sub>2</sub> film. These pores facilitates the permeation of FAI:MACl:MABr solution in the whole pbI<sub>2</sub> layer, which in turn would favor the full conversion of PbI<sub>2</sub> to final perovskite material. Fast conversion is of great importance in sequential deposition process because remnant PbI<sub>2</sub> can act as an insulate layer.

Cross sectional SEM images of layer after each step is provided in **Figure 6**. Comparing the **Figure 6a** and b it can be seen that the thickness value of PbI<sub>2</sub> is almost twice of PbS. According to **Figure 6c** the thickness of FAPbI<sub>3</sub>-based perovskite after converting PbI<sub>2</sub> increased by a factor of 2 again. We interpret the thickening of the deposited films by the volume expansion happening after chemical conversion at each step<sup>20,26</sup>. The volume expansion is attributed to variation of lattice parameters of PbS, PbI<sub>2</sub> and perovskite.

**Figure 6.**

Cross sectional SEM image of a) PbS, b) PbI<sub>2</sub> and c) FAPbI<sub>3</sub>-based films on mp-TiO<sub>2</sub>/bl-TiO<sub>2</sub>/FTO substrate obtained after each step of multi-step chemical bath deposition assisted synthesis of halide perovskite film.

**Figure 7** shows the UV absorption spectra of two samples prepared from two different PbI<sub>2</sub> layers. Both spectra show onsets of absorption at 810 nm. The optical band gap almost remains the same (1.55 eV) for

both films. The higher absorption of perovskite film based on 155°C -PbI<sub>2</sub> compared to perovskite film based on 120°C -PbI<sub>2</sub> might be correlated to the higher amount of perovskite in former one.

UV absorption spectra also confirm the formation of  $\alpha$ -phase of FAPbI<sub>3</sub> without any trace of  $\delta$ -phase. Because yellow phase of FAPbI<sub>3</sub> has characteristic absorption peak below 500 nm, whereas the both obtained spectra have shown a remarkable absorption in the visible range<sup>52</sup>.

Obtaining pure  $\alpha$ -phase of FAPbI<sub>3</sub> is of great importance for photovoltaic applications. The yellow  $\delta$ -FAPbI<sub>3</sub>, is a non-photoactive phase and due to having a chain-like structure prevents the transport of electrons and in turn reduces photovoltaic performance<sup>53</sup>.

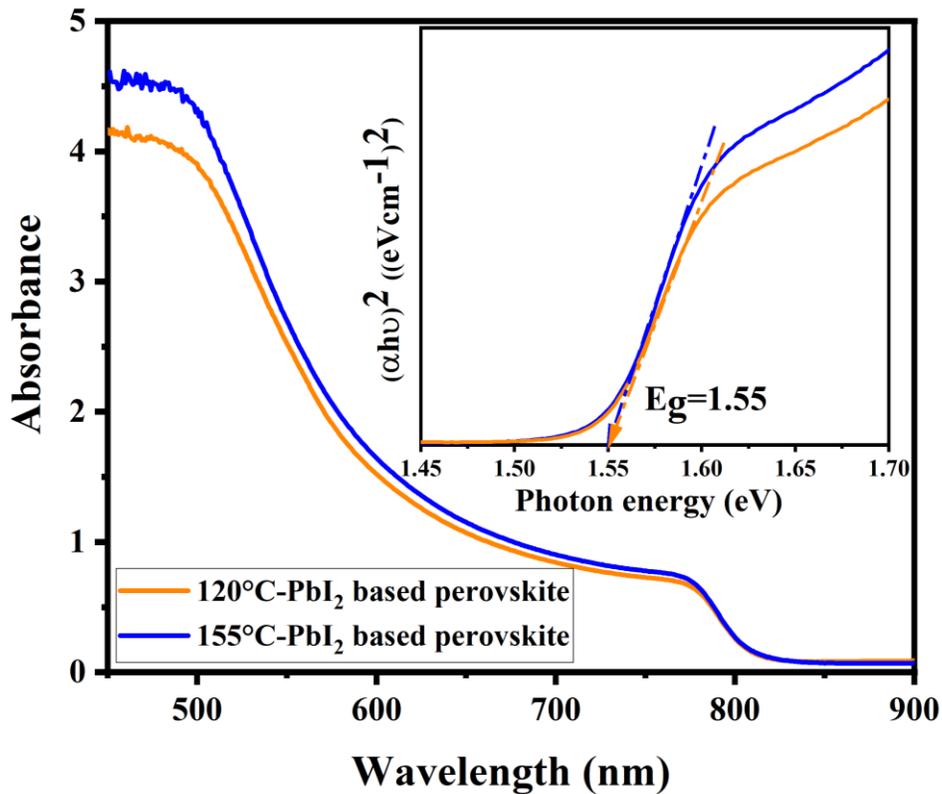

Figure 7.

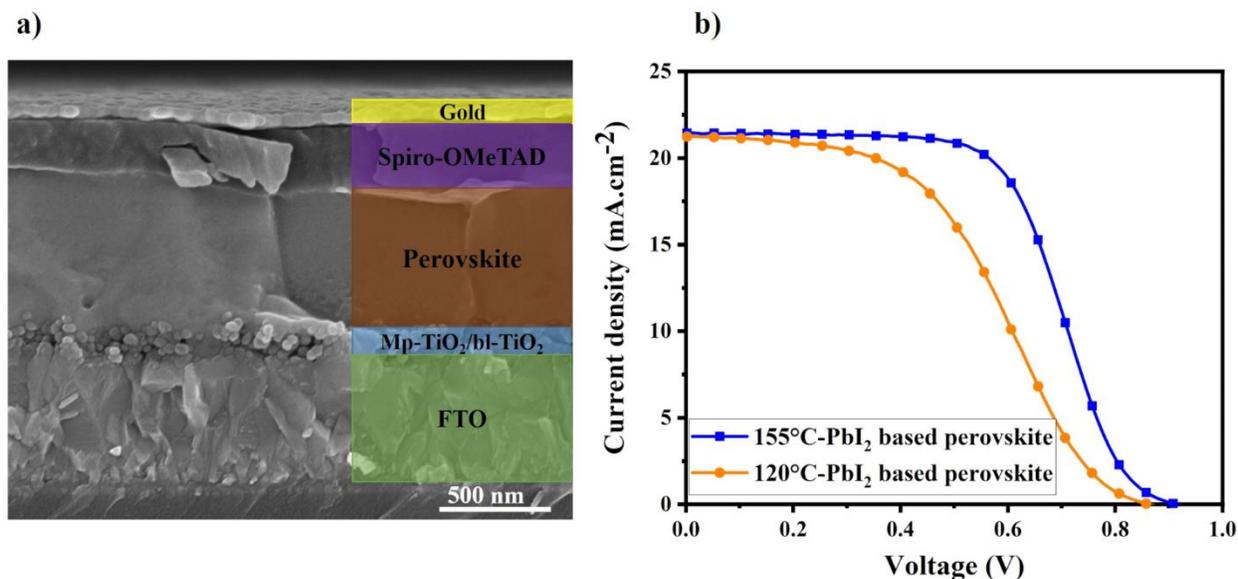

Absorption spectrum for the FAPbI<sub>3</sub>-based films produced from 120°C -PbI<sub>2</sub> and 155°C -PbI<sub>2</sub>.

### *PSC fabrication and device performance*

In order to investigate the photovoltaic applicability of the synthesized perovskite films, devices with configuration FTO/bl-TiO<sub>2</sub>/mp-TiO<sub>2</sub>/perovskite/spiro-OMeTAD/Au were made by using perovskite films obtained from three-step-method. **Figure 8a** shows the cross sectional view of the complete perovskite cell and the right part of image was colored and labeled to make a guide to position and thickness of each layer. It can be seen that perovskite film prepared by multi-step method has a columnar crystal grains which are elongated from bottom to top.

The related current density-voltage (J-V) curves of the best perovskite fabricated from perovskite based on 120°C -PbI<sub>2</sub> and 155°C -PbI<sub>2</sub> measured under AM 1.5G solar illumination at 100 mW cm<sup>-2</sup> and are plotted in **Figure 8b**. Also **Table 2** summarizes the photovoltaic parameters obtained from j-V curves, average values and corresponding standard deviation. **Tables S3 and S4** in the supplementary document shows photovoltaic parameters and error analysis derived from J-V curves of devices. As can be seen from **Table 2**, the best-performing cell fabricated via proposed method, demonstrates acceptable performance with a  $J_{sc}$  of 21.43 mA cm<sup>-2</sup>,  $V_{oc}$  of 0.918 V,  $FF$  of 57.67 and  $PCE$  of 11.35%. It can be seen that the  $J_{sc}$  of PSC based on 155°C -PbI<sub>2</sub> increased slightly compared that of 120°C-PbI<sub>2</sub> based perovskite. It can be related to PbI<sub>2</sub>-free and high crystalline perovskite synthesized from 155°C -PbI<sub>2</sub> which leads to increment of visible light absorption. Furthermore, in the device based on 120°C -PbI<sub>2</sub>, the leftover PbI<sub>2</sub> can hinder the electron transfer of perovskite film due to high resistivity of PbI<sub>2</sub> which in turn increases the possibility of charge carrier recombination and reduces  $V_{oc}$  and  $FF$ .

Totally, the performance of the device prepared by proposed three-step method is comparable with the performance of other devices made from uncommon metal precursor rather than PbI<sub>2</sub> and is the highest reported efficiency for CBD-based method of synthesizing perovskite. Nevertheless, the method is still less efficient compare to the conventional spin coating method and there are many rooms to modify different parameters of this method in order to enhancement of efficiency.

**Figure 8**

(a) Cross section SEM image of a FTO/bl-TiO<sub>2</sub>/mp-TiO<sub>2</sub>/perovskite/Spiro-OMeTAD/Au solar cell. b) Current-voltage characteristic of the best-performance devices based on 120°C -PbI<sub>2</sub> and 155°C -PbI<sub>2</sub>.

## Conclusion

Briefly, a scalable and environmentally friendly route was developed by using chemically deposited PbS from an aqueous solution as the precursor and created perovskite films with good quality and full coverage. The iodination temperature in second step was changed in a controlled way and the influence on final film quality was evaluated. Finally, well grown perovskite films with no unconverted PbI<sub>2</sub> had successfully synthesized by iodination the PbS layer at 155°C and exposing to the FAI:MACl:MABr/IPA solution which subsequently have been applied in solar cells with the following structure: FTO/bl-TiO<sub>2</sub>/mp-TiO<sub>2</sub>/perovskite/spiro-OMeTAD/ Au. The assembled solar cells represented the *PCE* of 11.35% with corresponding photocurrent of 21.43 mA cm<sup>-2</sup> and open circuit voltage of 0.918 V. CBD is a widely used industrial method, so the offered technique opens new avenue for large scale production of perovskite solar cells. Moreover, avoiding the use of toxic solvent especially DMF facilitates the green

fabrication of PSCs. It can be expected that the performance of devices made by this method will be enhanced via optimizing the various parameters of the deposition.

## **Materials and method**

*Preparation of electron transport layers-* Fluorine-doped tin oxide (FTO) substrates (Pilkington, TEC8,  $8 \Omega \text{ cm}^{-2}$ ) were undergone surface preparation including pattern etching and ultrasonically cleaning in acetone, detergent and ethanol for 30 min per each. A dense  $\text{TiO}_2$  blocking layer (bl- $\text{TiO}_2$ ) was deposited on the FTO via the spray pyrolysis method from a solution of titanium diisopropoxide bis(acetylacetonate) (Aldrich) diluted in ethanol (v/v, 1/10) at  $450^\circ\text{C}$ . Then, a 200-nm thick mesoporous  $\text{TiO}_2$  (mp- $\text{TiO}_2$ ) layer was fabricated on the substrates by spin coating a  $\text{TiO}_2$  commercial paste (containing  $\text{TiO}_2$  nanoparticles: average diameter: 50 nm, anatase) diluted in 2-methoxyethanol and terpineol (Aldrich) solution followed by annealing at  $500^\circ\text{C}$  for 60 min and cooling to room temperature.

*Synthesizing of the perovskite film-* a three-step deposition method was employed to produce the perovskite film. Initially a PbS layer was coated on substrates via chemical bath deposition method. The deposition bath contained 85 ml of an aqueous solution, consisting of 2.5 ml  $\text{Pb}(\text{CH}_3\text{COO})_2 \cdot 3\text{H}_2\text{O}$  (Sigma-Aldrich) 1 M, 6 ml thiourea  $\text{SC}(\text{NH}_2)_2$  (Sigma-Aldrich) 1 M, 10 ml NaOH (Aldrich) 1M and 2 ml triethanolamine (Sigma) 1 M. The deposition was performed at room temperature. Afterward, the PbS layers and iodine chips (Sigma-Aldrich) were put inside one petri dish on different temperatures to chemically convert PbS to  $\text{PbI}_2$ . Next,  $\text{PbI}_2$  films were exposed to a FAI:MACl:MABr solution ( $85:10:10 \text{ mg ml}^{-1}$ ) and then spun at 5000 rpm for 30 s. The selection of solution was based on a comparison between the qualities of perovskite films obtained by different solutions as shown in **Figure S2**. After two step annealing at  $150^\circ\text{C}$  and  $100^\circ\text{C}$  for 30 min per each, the conversion of  $\text{PbI}_2$  to perovskite film was completed.

*Assembling perovskite solar cells (PSCs)-* After preparing  $\text{FAPbI}_3$ -based perovskite/ mp- $\text{TiO}_2$  /bl- $\text{TiO}_2$ , a 2,20, 7,70-tetrakis (N,N-di-pmethoxyphenylamino)-9,90 - spirobifluorene (spiro – OMeTAD, Lumtec)

processor solution (100 mg of spiro-OMeTAD, 39 ml of 4-tert-butylpyridine (Aldrich), 23 ml of bis (trifluoromethane) sulfonamide lithium salt (Li-TFSI, Aldrich) solution and 10 ml of cobalt salt (Lumtec solution per 1.1 ml chlorobenzene) was spin coated onto the as-deposited perovskite film described above at 3000 rpm for 30 s. Finally, for completing the device an 80 nm gold film was coated on top of layers through thermal evaporation method.

*Characterization*-The thickness of the deposited and chemically converted solid state thin films were measured by a stylus profiler (KLA Tencor). The morphologies of the films were examined using a scanning electron microscopy (SEM, S-4800, Hitach High-Technologies) and atomic force microscopy (AFM, MultiMode V Veeco). Energy dispersive X-ray analysis (EDX) is done in conjunction with SEM. Crystalline structure of the films were determined by using a X-ray diffractometer (XRD, D8 ADVANCE, Bruker AXS) with Cu K $\alpha$  radiation ( $\lambda=1.5405 \text{ \AA}$ ).

In order to estimate the degree of crystalline orientation in different directions, the texture coefficient (*TC*) was calculated by **Equation 6**<sup>46</sup>:

$$TC(hkl) = \frac{I(hkl)/I_0(hkl)}{[\sum I(hkl)/I_0(hkl)]/N} \quad 6$$

Where  $I(hkl)$  is the intensity of measured peak,  $I_0(hkl)$  is the intensity of reference data peak for random oriented powder, and  $N$  is the number of measured peaks.

The absorption spectrum of final perovskite layers was extracted using a UV-vis spectrophotometer (Jasco V-780). In order to record current-voltage (J-V) graphs, A Keithley 2400 source meter was used and Illumination of air mass (AM) 1.5 G and a power of  $100 \text{ mW cm}^{-2}$  was applied by a solar simulator (Newport, Oriel Class A, 91195A). For setting the correct irradiance of solar simulator, a calibrated Si reference cell certified by National Renewable Energy Laboratory (NREL) was used.

## Author contributions

F.N. and S.G. together conceived the research idea. F.N. initiated, conceptualized and supervised the research project. S.G. have carried out experiments. All the authors have analyzed and discussed the results thoroughly. S.G. and F.N. wrote the manuscript with inputs from S.I.S. and all authors contributed and approved the final version of the manuscript.
