13 **Abstract**

14 **Background:** Black spruce (*Picea mariana* (Mill.) BSP)-forested peatlands are widespread
15 ecosystems in boreal North America in which peat accumulation, known as the paludification
16 process, has been shown to induce forest growth decline. However, the ecophysiological
17 mechanisms that lead to growth reductions in black spruce remain unexplored. Trees growing in
18 paludified forests have to deal with continuously evolving environmental conditions (e.g., water
19 table rise, increasing peat thickness) that may require growth mechanism adjustments over time. In
20 this study, we investigated tree ecophysiological mechanisms along a paludification gradient in a
21 boreal forested peatland of eastern Canada by combining peat-based and tree-ring analyses. Carbon
22 and oxygen stable isotopes in tree rings were used to document changes in carbon assimilation
23 rates, stomatal conductance, and water use efficiency. In addition, paleohydrological analyses were

24 performed to evaluate the dynamical ecophysiological adjustments of black spruce trees to site-
25 specific water table variations.

26 **Results:** Increasing peat accumulation considerably impacted forest growth, but no significant
27 differences in tree water use efficiency (iWUE) were observed between the study sites. Tree-ring
28 isotopic analysis indicates no iWUE decrease over the last 100 years, but rather an important
29 increase at each site up to the 1980s, before iWUE stabilized. Surprisingly, inferred basal area
30 increments did not reflect such trends. Our results suggest that the slower growth rates observed at
31 the most paludified sites are attributable, at least partially, to both lower carbon assimilation rates
32 and stomatal conductance. These findings show that iWUE variations do not necessarily reflect tree
33 ecophysiological adjustments required by changes in growing conditions. Local water table
34 variations induced no changes in ecophysiological mechanisms, but the synchronous shift in iWUE
35 observed at all sites in the mid-1980s suggests a tree response to regional or global factors, such as
36 increasing atmospheric CO₂ concentration.

37 **Conclusions:** Our study shows that paludification induces black spruce growth decline without,
38 however, altering tree water use efficiency in boreal forested peatlands. This is the first attempt in
39 exploring the complex interactions between stem growth, ecophysiological mechanisms, and
40 environmental conditions in paludified sites. Additional research on carbon allocation strategies is
41 of utmost importance to understand the carbon sink capacity of these widespread ecosystems and
42 better predict their response to future climate change.

43

45 forested peatland, paludification, stable isotope, water use efficiency

46

47 **Background**

48 Black-spruce (*Picea mariana* (Mill.) BSP)-dominated forested peatlands are widespread
49 ecosystems in boreal North America (Korhola 1995; Crawford et al. 2003; Lavoie et al. 2005). In
50 such environments, *Sphagnum* moss growth is favored and leads to the development of thick
51 organic layers that maintain cool, acid, humid, and anaerobic soil conditions (Van Cleve et al. 1983;
52 Fenton and Bergeron 2006). As this paludification process progresses, soil temperature and
53 nutrients become limiting, and forest growth eventually declines (Boudreault et al. 2002; Harper et
54 al. 2003; Simard et al. 2007; Lafleur et al. 2011), leading to tree dieback and an opening of forest
55 stands. This negatively impacts the forest productivity and, therefore, several management
56 practices have been developed to reduce or even reverse this process (e.g., Lavoie et al. 2005;
57 Bergeron et al. 2007; Fenton et al. 2009). However, there is still a need to shed light on the
58 mechanisms that control forest growth decline in paludified ecosystems in order to enhance our
59 capacity to localize and anticipate the effects of paludification on forest productivity, and thus
60 optimize management decisions.

61

62 While tree growth decline represents a well-established consequence of the paludification process,
63 ecophysiological mechanisms that lead to growth reductions in black spruce remain unexplored.
64 Based on existing ecophysiological theory (mostly developed in non-paludified sites), three
65 mechanisms may possibly be invoked either jointly or separately to explain such declines. First,
66 paludification process may reduce carbon assimilation rates (A), as it is well known that the
67 photosynthesis apparatus of plants is sensitive to thermal (Göbel et al. 2019), oxygen
68 (Bartholomeus et al. 2008) or nutrient limitations (Longstreth and Nobel 1980). A reduction in A
69 would imply the downregulation of gross primary production (GPP) and less photosynthates export
70 to stem growth. In temperate environments, such a positive relationship between GPP and stem
71 growth has been elucidated (Belmecheri et al. 2014), but this relationship is far from being

72 applicable to boreal and paludified forests. In boreal environments, relationships between carbon
73 uptake and forest growth are either inconclusive (Rocha et al. 2006) or decoupled (Pappas et al.
74 2020), while remaining unexplored in paludified ecosystems. Second, growth decline could also
75 result from a reduction of stomatal conductance (g_s). When trees are severely affected by drought
76 stress, stomatal closure allows plants to reduce water losses during transpiration, but this
77 mechanism also penalizes carbon uptake and ultimately results in lower growth rates (Linares and
78 Camarero 2012). However, in paludified environments, adjustments of plant stomata to peat
79 accumulation, climate variability, and water table variations are yet to be determined. Lastly, trees
80 growing in nutrient-poor/low oxygen settings are more susceptible to allocate carbon to the root
81 system rather than to aboveground components (Giardina et al. 2003; Vicca et al. 2012). Thus,
82 changes in carbon allocation strategies favoring belowground biomass as peat accumulates could
83 explain the apparent growth decrease visible in stems.

84

85 Another source of uncertainties arises from the fact that trees growing in paludified ecosystems
86 have to deal with continuously evolving environmental conditions. The accumulation of thick
87 organic layers induces significant changes that highlight the dynamic interactions occurring in
88 boreal forested peatlands. For example, paludification is characterized by water table rise (Lavoie
89 et al. 2005; Fenton and Bergeron 2006), and interactions over time may exist between water table
90 fluctuations, stem growth, and tree water use efficiency (i.e., the ratio of carbon assimilated to water
91 losses through evapotranspiration; Farquhar et al. 1989). These interactions, which remains largely
92 unexplored, may vary in function of the degree of paludification (i.e., organic layer thickness).
93 Consequently, how growth mechanisms adjust to such changes and how they impact tree radial
94 growth over time needs to be addressed.

95

96 Carbon and oxygen stable isotopes in tree-ring cellulose may be of great help to disentangle
97 processes responsible for tree growth decline in paludified environments. Indeed, gas exchange

98 dynamics at the leaf-atmosphere interface are imprinted in the isotopic signature of annually-
99 produced wood. For example, both A and g_s affect carbon stable isotope fractionation in tree-ring
100 cellulose (Scheidegger et al. 2000; Cernusak et al. 2013), and the ratio between both, namely
101 intrinsic water use efficiency ($iWUE=A/g_s$), is at the core of ecosystem functioning (Guerrieri et al.
102 2019). Moreover, fractionation of oxygen stable isotopes reflects the magnitude of stomatal
103 controls (through g_s) on transpiration jointly with the signal of source water uptake (Barbour 2007).
104 Tree-ring based analysis of $\delta^{13}C$ and $\delta^{18}O$ can help tracking dynamical adjustments of
105 ecophysiological parameters to changing environmental conditions (Voelker et al. 2016). Such
106 strategies have been well studied for well-drained environments (Frank et al. 2015; Voelker et al.
107 2016), but have never been investigated for paludified sites. In addition, the use of a paleoecological
108 approach may be useful to investigate the interactions between tree growth mechanisms and local
109 environmental conditions in boreal forested peatlands. Analyses of peat cores are commonly used
110 to document, among others, past changes in both vegetation composition and hydrological
111 conditions. For example, testate amoeba (unicellular protists) shells preserved in peat are widely
112 used proxies for reconstructing variations in water table depths (Mitchell et al. 2008). Such
113 paleoecological and paleohydrological analyses have previously been conducted in forested
114 peatlands (Ruppel et al. 2013; Le Stum-Boivin et al. 2019; Magnan et al. 2019), but have never
115 been put in relation to tree growth.

116

117 In this study, we aim to improve our knowledge of the mechanisms that are driving tree growth
118 decline observed in black-spruce-dominated forested peatlands of eastern Canada. To do this, we
119 compare tree-ring-derived growth trends and stable-isotope-inferred ecophysiological processes
120 along a paludification gradient characterized by increasingly thicker peat deposits. More
121 specifically, the objectives of the study are to (1) determine whether the decline in stem growth
122 induced by the paludification process is attributable to changes in ecophysiological processes (such
123 as A or g_s) and/or to changes in carbon allocation strategies, and (2) evaluate the dynamical

124 ecophysiological adjustments to ever-changing environmental conditions. We hypothesised that (1)
125 growth decline results from a reduction of water use efficiency (iWUE), (2) reductions in iWUE
126 are greater in the most paludified sites, and (3) strongest ecophysiological adaptation also take place
127 in the most paludified sites. In order to test these hypotheses, we used an innovative approach that
128 combines peat-based paleohydrological analyses – to reconstruct past variations in water table
129 depth – and stable isotope analyses in tree rings – to investigate iWUE changes through time.

130

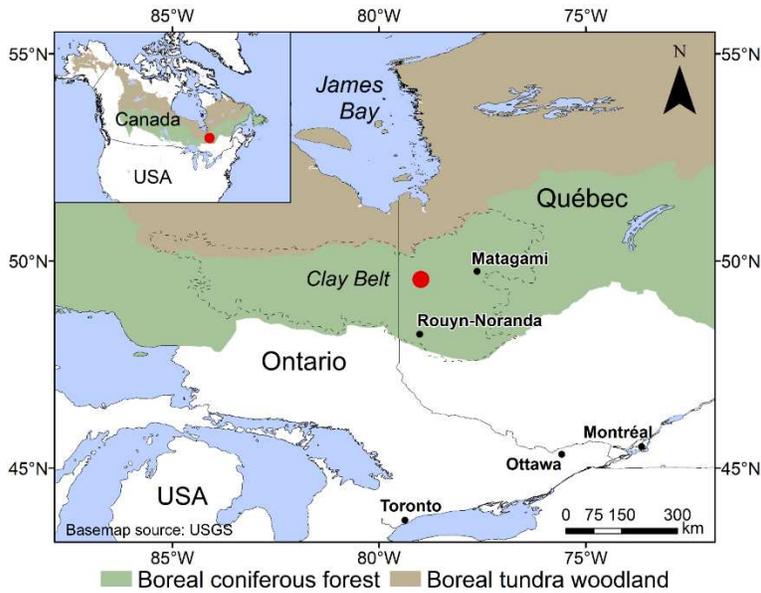

131 **Methods**

132 **Study area**

133 The study was conducted south of James Bay in eastern Canada, within the Clay Belt region part
134 of the black spruce-feather moss bioclimatic domain (Saucier et al. 2009; Fig. 1). This area is
135 particularly prone to paludification due to the relatively cold and humid climate, the flat
136 topography, and the dominance of poorly-drained clayey sediments left by the proglacial lakes
137 Barlow and Ojibway (Vincent and Hardy 1977). Mean annual temperature is 0.3°C (over the 1950-
138 2013 period), ranging from -18.9°C in January to 16.3°C in July, and mean annual precipitation is
139 818 mm (McKenney et al. 2011). The regional fire cycle is estimated at ~400 years since 1920
140 (Bergeron et al. 2004), allowing the accumulation of thick organic layers in forests between fire
141 events.

142

143

144

145 **Figure 1. Location of the studied Casa boreal forested peatland (red dot).**

146

147 **Site selection and sampling**

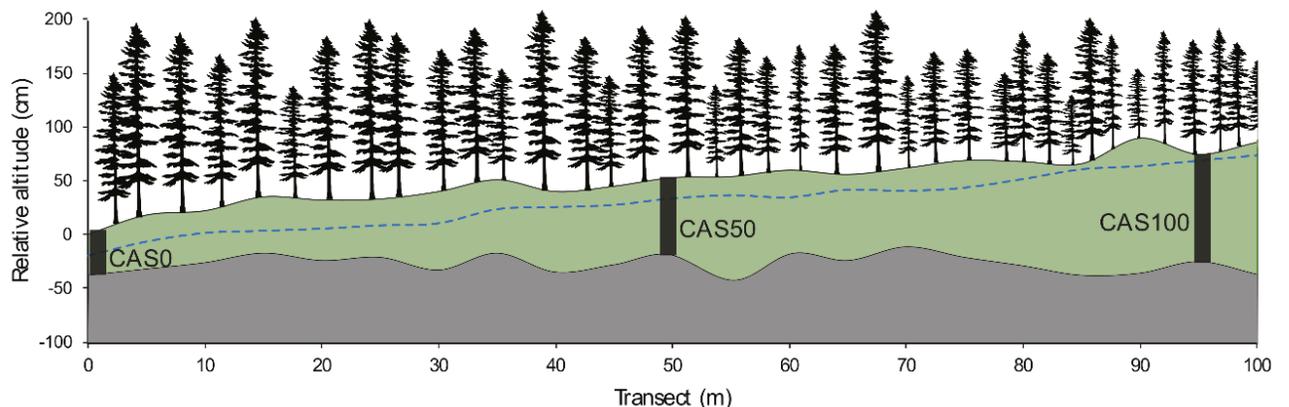

148 The Casa forested peatland (49°33'06"N, 78°59'10"O; Fig. S2.1) was selected following the studies
 149 of Magnan et al. (2020) and Le Stum-Boivin et al. (2019) due to its regional representativeness in
 150 terms of topography, vegetation composition, and canopy openness. The slope is <1% and the
 151 organic layer thickness varies between 40 cm and more than 1 m along the selected transect. The
 152 canopy cover is relatively closed but gradually opens up with organic layer thickening, which is
 153 typically observed in forested peatlands of the Clay Belt. The aboveground vegetation is largely
 154 dominated by black spruce and ericaceous shrubs, such as *Vaccinium angustifolium*, *Rhododendron*
 155 *groenlandicum*, *Kalmia angustifolia*, and *Chamaedaphne calyculata*. The understory is dominated
 156 by *Sphagnum* communities, particularly *S. angustifolium/fallax* under the tree canopy, and *S.*
 157 *fuscum* where the canopy cover is more open.

158

159 Three sampling sites (CAS0, CAS50, CAS100) were established along a 100 m transect following
 160 an organic matter thickness gradient within the selected forested peatland (Fig. 2). At each site, one

161 peat monolith was sampled down to the mineral contact using a Box corer (Jeglum et al. 1992).
162 Sampling locations were chosen to be representative of the degree of paludification of each site in
163 terms of peat thickness and canopy opening. Relative surface altitude and peat thickness were
164 measured at 5 m intervals along the transect using a high precision altimeter (ZIPLEVEL PRO-
165 2000) and an Oakfield probe. Water table depths were measured at the same intervals, in June 2017
166 and September 2018, a few hours after holes were dug to make sure that the water table level had
167 stabilized. Twenty black spruce trees were also sampled at each site within a 10 m radius of the
168 collected peat core. Only dominant and codominant trees with straight stems and no visible scars
169 were selected. Peat thickness was measured at the bottom of each sampled tree to validate the
170 concordance with the mean peat thickness of the site. The diameter at breast height (DBH) and the
171 height of selected trees were measured and cross-sections were collected at standard height (1.3 m).
172 The root system of one black spruce tree per site was excavated to verify the depth of the rooting
173 zone and the growth substrate (i.e., mineral or organic matter). Moreover, tree aboveground
174 biomass of each site was estimated by measuring the diameter at breast height (DBH) of all trees
175 (DBH ≥ 1 cm) within a 10 \times 10 m plot and then using allometric equations adapted to black spruce
176 growth (Ung et al. 2008).

177

178

179 **Figure 2. Schematic of the three sites along the study transect.** Relative altitude of the organic
180 layer (green) and the mineral surface (grey) are shown. Black rectangles represent the location of

181 the sampled peat cores. The dotted blue line indicates the depth of the water table measured in the
182 field. Trees are not to scale but are representative of variations in canopy openness along the
183 transect.

184

185 **Black spruce radial growth analysis**

186 The sixty dried cross-sections were finely sanded (from 80 to 600 grit size) prior to ring-width
187 measurements along two radii using CooRecorder software (version 8.1.1; Larson 2016). Samples
188 were visually cross-dated using PAST5 software (version 5.0.610; Knibbe 2019), and skeleton plots
189 were generated using the R package *dplR* (version 1.6.9; Bunn et al. 2018). Ring-width series were
190 converted to annual basal area increment (BAI) to compare tree aboveground productivity between
191 the three sites, as BAI is more representative of three-dimensional stem growth than the linear ring-
192 width measurements (Husch et al. 2003; Biondi and Qeadan 2008). Individual BAI series were
193 produced using the R package *dplR* (version 1.6.9; Bunn et al. 2018), and yearly averages were
194 then calculated using all trees from the same site. Ring-width series were also standardized (Fig.
195 2.6) in order to perform correlation analyses with climate data (SM 1.1).

196

197 **Isotopic analysis of tree rings**

198 Black spruce ecophysiological processes were evaluated from carbon ($\delta^{13}\text{C}$) and oxygen ($\delta^{18}\text{O}$)
199 isotopic ratio analyses. These were performed on five trees per site and from two wood strips per
200 tree (i.e., a total of 30 samples). Sample preparation was carried out following the protocol
201 described in Giguère-Croteau et al. (2019) (SM 1.2). A five-year resolution over a 100-year period
202 (1919-2018) was considered. Alpha-cellulose was extracted, as suggested for black spruce samples
203 (Bégin et al. 2015), following the protocol used by Naulier et al. (2014).

204

205 Tree-ring $\delta^{13}\text{C}$ values vary according to discrimination against ^{13}C during photosynthesis, defined
206 as (Farquhar et al. 1982):

207

$$208 \quad \Delta^{13}\text{C} = \frac{\delta^{13}\text{C}_{\text{air}} - \delta^{13}\text{C}_{\text{tree}}}{1 + (\delta^{13}\text{C}_{\text{tree}}/1000)}, \quad (1)$$

209 where $\delta^{13}\text{C}_{\text{air}}$ is the carbon isotope ratio of the atmosphere and $\delta^{13}\text{C}_{\text{tree}}$ is the isotopic value of the
210 tree ring. $\delta^{13}\text{C}_{\text{air}}$ values were taken from McCarroll and Loader (2004) for the 1919-2003 period,
211 and were linearly extrapolated for the 2004-2018 period. Because of the five-year resolution of
212 $\delta^{13}\text{C}_{\text{tree}}$ values, we averaged the $\delta^{13}\text{C}_{\text{air}}$ values over five years. Following Farquhar et al. (1989),
213 $\Delta^{13}\text{C}$ is related to leaf intercellular CO_2 concentration (c_i) and ambient CO_2 concentration (c_a)
214 according to the following equation:

215

$$216 \quad \Delta^{13}\text{C} = a + (b - a) \left(\frac{c_i}{c_a} \right), \quad (2)$$

217 where a (4.4‰) is the fractionation occurring during CO_2 diffusion through stomata (O’Leary
218 1981) and b (27‰) is the fractionation due to carboxylation by the Rubisco enzyme (Farquhar and
219 Richards 1984). Values of c_a were obtained from the Mauna Loa Observatory
220 (esrl.noaa.gov/gmd/ccgg/). Intrinsic water use efficiency (iWUE), defined as the amount of carbon
221 assimilated per unit of water lost, can then be estimated from c_i and c_a as follows (Ehleringer et al.
222 1993):

223

$$224 \quad \text{iWUE} = \left(\frac{A}{g_s} \right) = \left(\frac{c_a - c_i}{1.6} \right), \quad (3)$$

225 where A is the rate of CO_2 assimilation, g_s is the stomatal conductance, and the constant 1.6
226 represents the ratio of water vapor and CO_2 diffusivity in air. Equation 3 shows that the difference
227 between c_a and c_i is related to the ratio of assimilation (A) to stomatal conductance (g_s).

228

229 Since the $\delta^{18}\text{O}$ composition of tree rings is mainly controlled by leaf water composition and
230 enrichment due to transpiration of lighter oxygen isotopes, $\delta^{18}\text{O}$ values are assumed to be related
231 to the stomatal conductance and independent of photosynthetic activity (Yakir 1992; Barbour
232 2007). Therefore, by combining $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ analyses it is possible to discriminate the effects of
233 changes in photosynthetic rate (A) and stomatal behavior (g_s) on $i\text{WUE}$ (Scheidegger et al. 2000).

234

235 **Peat-based paleoecohydrological reconstructions**

236 In order to evaluate the response of black spruce ecophysiological mechanisms to hydrological
237 variations, water table depths were reconstructed from peat core analyses. The collected cores were
238 cut into 1 cm-thick slices before analysing testate amoeba assemblages at 1 cm intervals. Testate
239 amoeba shells were extracted following the standard protocol of Booth et al. (2010) (SM 1.3).
240 Samples were then analysed under an optical microscope (400 \times magnification). A minimum of 100
241 tests was counted per sample, except in highly humified peat samples, in which test concentration
242 was very low. In these cases, no water table depth (WTD) was inferred, as the total count (< 20
243 tests) was insufficient to ensure reliable WTD reconstruction (Payne and Mitchell 2009). Past
244 WTDs were reconstructed using a weighted average model with tolerance down-weighting and
245 inverse deshrinking (WA.inv.tol). The transfer function was built using the R package *rioja*
246 (version 0.9-15.1; Juggins 2017), from a modern dataset of 272 surface samples combining non-
247 forested (Lamarre et al. 2013) and forested peatlands (Beaulne et al. 2018 and this study) of eastern
248 Canada. High inferred WTD values corresponded to drier surface conditions.

249

250 Plant macrofossils and macroscopic charcoal particles (>0.5 mm) were also analysed along each
251 peat core to reconstruct vegetation dynamics since peat initiation and better understand the
252 paludification process at each site (SM 1.4).

253

254 **Peat core chronologies**

255 A total of 11 samples were submitted to A. E. Lalonde AMS Laboratory (University of Ottawa,
256 Canada) for accelerator mass spectrometry radiocarbon dating (^{14}C). Plant macrofossil remains
257 were carefully selected to date peat initiation, the last fire event, and main transitions in vegetation
258 composition at each sampling site (Beaulne et al. under review). The ^{14}C dates were calibrated
259 using the IntCal13 calibration curve (Reimer et al. 2013). ^{210}Pb dating was also achieved for the
260 uppermost 24-26 cm of peat cores at 1 cm intervals by alpha spectrometry (EGG Ortec 476A) at
261 the GEOTOP Research Center (Université du Québec à Montréal, Canada). Ages were inferred by
262 ^{210}Po activity measurement, using the constant rate of supply model (Appleby and Oldfield 1978)
263 following $\text{HNO}_3\text{-HCl-H}_2\text{O}_2$ sample digestion (Ali et al. 2008). Age-depth models were generated
264 using the *rbacon* package in R (version 2.3.9.1; Blaauw and Christen 2019). Ages are expressed in
265 calendar years before present (cal yr BP; 1950 CE) and the age of the peat surface is therefore set
266 to -67 cal yr BP (coring year: 2017 CE).

267

268 **Statistical analyses**

269 Statistical analyses were achieved to compare data in function of the degree of paludification. One-
270 way ANOVA analyses were performed to test for differences in BAIs, WTDs, $\delta^{13}\text{C}$ -derived
271 ecophysiological parameters, and tree-ring $\delta^{18}\text{O}$ between sites. In the case where dissimilarities
272 were observed between the study sites, multiple comparisons of means were further computed from
273 post-hoc Tukey HSD test to identify significant differences. Breakpoints in slopes were also

274 estimated from Davies test (Davies 1987) for $\delta^{13}\text{C}$ -derived ecophysiological parameters, tree-ring
275 $\delta^{18}\text{O}$, and WTDs. All these statistical analyses were performed in R (R Core Team 2018).

276

277 **Results**

278 The study sites CAS0, CAS50, and CAS100 have an organic layer thickness of 40, 73, and 98 cm,
279 respectively (Table 1). Tree-ring analyses revealed even-aged stands covering the period 1839-
280 2018 CE at each site (see sample depth in Fig. 3 for tree age variability). Radiocarbon dating of the
281 most recent charcoal layer indicates that the last fire event occurred between 0 and 290 cal yr BP
282 (median age: 175-179 cal yr BP; Table S2.1). These results suggest that trees were from the first
283 cohort that grew after the last local fire, which most likely occurred around 200-250 years ago
284 (~1800 CE). The depth of the uppermost charcoal layer in the peat profile indicates that black
285 spruce established in a residual organic layer of 15, 45, and 65 cm at sites CAS0, CAS50, and
286 CAS100 respectively. The root system excavation of the three selected trees suggests that roots
287 reached the mineral soil at CAS0 and CAS50, but were restricted to the organic layer at CAS100.

288

289 **Table 1. Characteristics of the three study sites ^a.**

Site	Mean organic layer thickness (cm)	Core length (cm)	Mean WTD (cm)	Mean DBH (cm)	Trees (n)	Tree aboveground biomass (kg m ⁻²)	Tree density ^b (trees ha ⁻¹)	Mean tree height ^c (m)
CAS0	40±5	38	25±2	10.4±2.1	20	8.9±0.3	1200	13.8±0.4
CAS50	73±4	69	20±1	9.4±1.4	24	7.6±0.3	1200	11.3±0.5
CAS100	98±4	95	10±2	5.6±0.9	34	4.6±0.2	1000	10.4±0.5

290 ^a ± values correspond to standard errors.

291 ^b Include trees with a diameter at breast height (DBH) ≥ 9 cm.

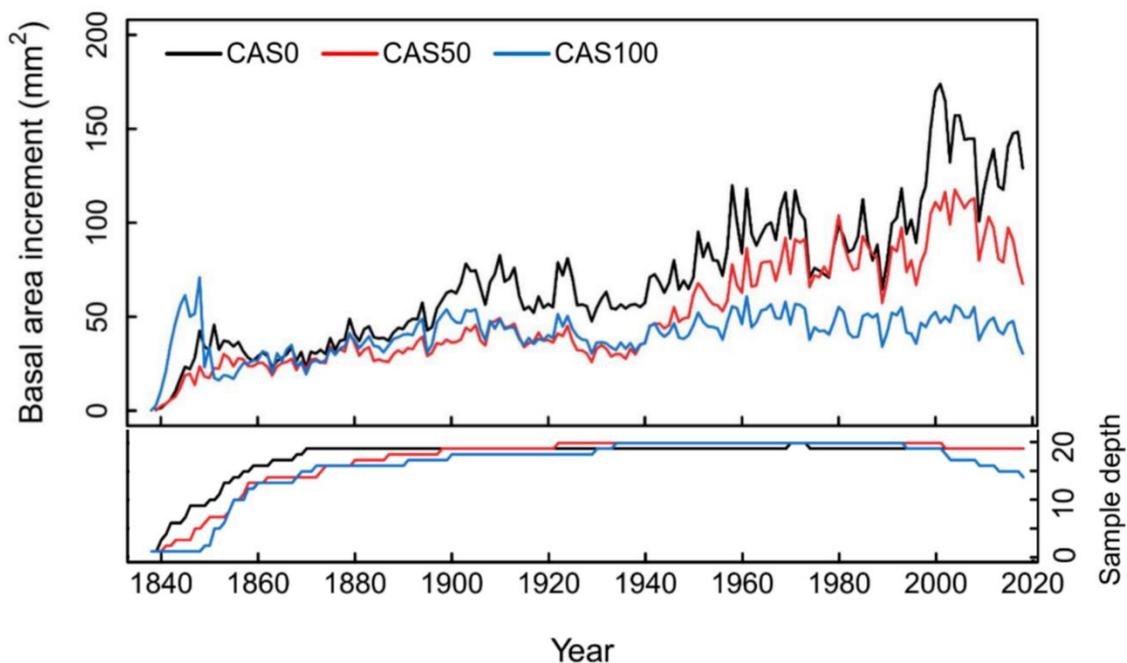

292 ^c Calculated from the twenty black spruce trees (dominant and co-dominant) sampled at each site.

293

294 **Black spruce radial growth**

295 Tree height and DBH values decrease along the paludification gradient, with the lowest values
 296 observed at the most paludified site (thickest organic layers) (Table 1). Mean DBHs of 10.4, 9.4,
 297 and 5.6 cm were calculated for CAS0, CAS50, and CAS100, respectively. BAIs also indicate a
 298 significant decrease in stem growth rates with increasing peat thickness (ANOVA $F=53.97$,
 299 $P<0.01$; Fig. 3, S2.3). Trees from CAS0 added a greater wood surface with age, resulting in an
 300 increasing BAI trend (mean BAI=70 mm²). At CAS50, tree radial growth followed similar patterns
 301 but was more limited (mean BAI=51 mm²). In contrast, trees from CAS100 maintained relatively
 302 constant BAI values, resulting in decreased wood production (mean BAI=40 mm²). Estimates of
 303 tree aboveground biomass showed similar trends with values of 8.9, 7.6, and 4.6 kg/m² for sites
 304 CAS0, CAS50, and CAS100, respectively.

305

306

307 **Figure 3. Mean annual basal area increment of black spruce trees since their establishment**
 308 **after the last fire event.** The decrease in sample depth (*n* trees) at CAS100 since 2000 is explained
 309 by some trees for which the latest rings were partly absent. See Fig. S2.3 for BAI distribution.

310

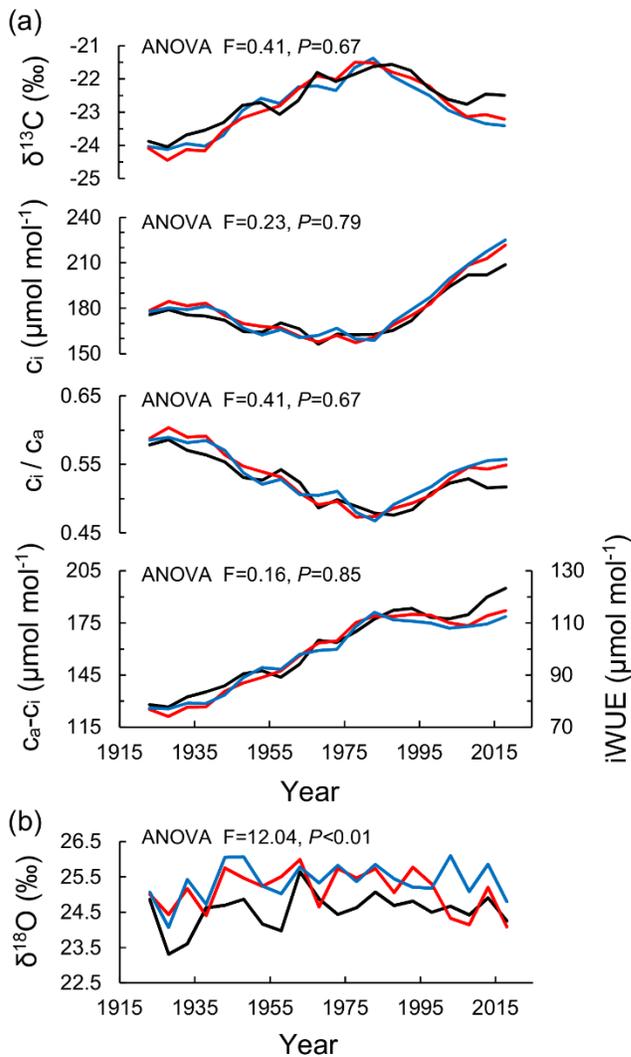

311 **Trends in $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and iWUE**

312 The $\delta^{13}\text{C}$ -derived ecophysiological parameters do not differ between the three sites over the 1919-
313 2000 period (Fig. 4a, ANOVAs $P>0.05$). Over time, black spruce trees used two different strategies
314 in response to rising c_a . A substantial increase in iWUE was first observed until the 1980s
315 ($c_a \approx 340$ ppm), along with relatively stable intercellular CO_2 concentration (c_i). During this
316 period, iWUE increased by 43% at each site. A major shift in tree ecophysiology then occurred in
317 the mid-1980s as c_i began to increase considerably (breakpoint=1984-1985, $P<0.01$). In parallel,
318 iWUE stabilized until 2018, except for at CAS0, where a new increase seems to have begun around
319 2000. However, this recent trend at CAS0 should be interpreted with caution considering its short
320 duration and the five-year resolution.

321

322 Tree-ring cellulose $\delta^{18}\text{O}$ analyses show no significant trends for the three sites across the whole
323 record (Fig. 4b, ANOVA $P<0.01$). However, oxygen stable isotope ratios were systematically
324 lower at the least paludified site (CAS0), suggesting a greater depletion in heavy isotopes (Tukey's
325 test $P<0.01$). For all series, tree-ring $\delta^{18}\text{O}$ values increased until ~1950 and became more constant
326 afterwards, except for a slightly decrease in the early 2000s at CAS50.

327

328

332 **CAS0, CAS50, and CAS100 are shown in black, red, and blue, respectively.**

333

334 **Paleoecohydrological reconstructions**

335 Both hydrological conditions and vegetation composition were similar between the three sites

336 throughout the duration of black spruce growth (Fig. S2.4, S2.5). Macrofossil analysis showed that

337 the last fire (~1800 CE) induced a shift in vegetation composition from high dominance of woody

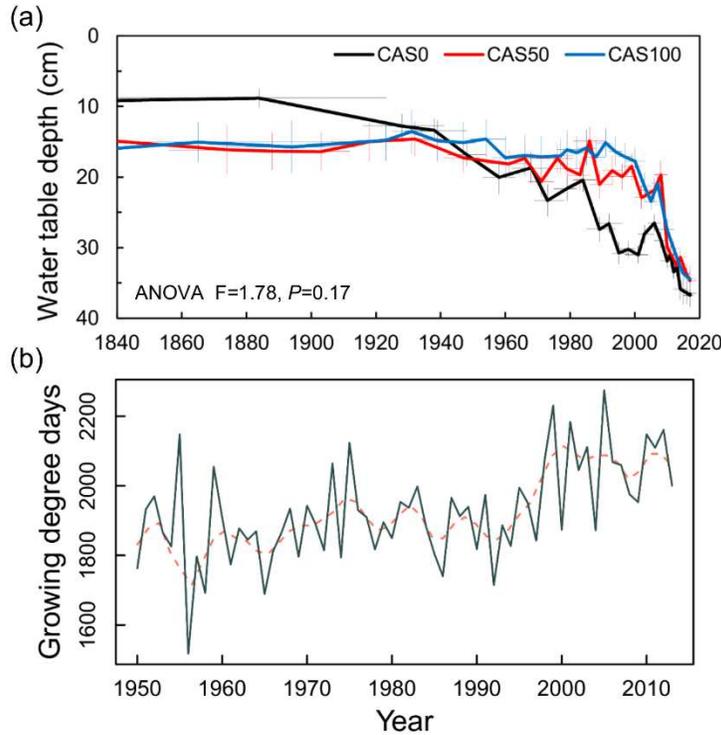

338 vegetation to a black spruce-*Sphagnum*-dominated stand (Fig. S2.3). The canopy opening allowed
339 rapid *Sphagnum* moss expansion in the bryophyte layer while the black spruce post-fire cohort
340 established.

341

342 Testate amoeba records indicate relatively wet conditions (high water table levels) shortly after the
343 fire, followed by a gradual lowering of the water table at the three sites (Fig. 5a, S2.5). Inferred
344 WTD values show very similar hydrological conditions at CAS50 and CAS100 during the post-
345 fire period (1840-2017). Both sites had stable WTD between 15 and 20 cm before water tables
346 deepened during the 2000s (breakpoint=2000, $P<0.01$), particularly in the very recent horizons
347 (~2010), while the water table lowered more gradually at CAS0 (breakpoint=1938, $P<0.01$). It
348 remains unclear whether the apparent drying trend reflects increasingly drier surface conditions or
349 simply an enhanced vertical growth of *Sphagnum* mosses that disconnected the peat surface from
350 the water table. Indeed, warmer conditions observed since the 1990s (Fig. S2.5) have led to
351 increasing growing degree days (Fig. 5b), which could have promoted this rapid peat accumulation.

352

353

354

355 **Figure 5. (a) WTD reconstructions for the post-fire period based on testate amoeba records**
 356 **and (b) growing degree days (>0°C) from May to September in the study area for the period**
 357 **1950-2013.** Error bars of both WTD reconstructions and age-depth modelling are shown by pale
 358 thin lines. Climate data were extracted from McKenney et al. (2011). A 10-year loess smoothing is
 359 shown by the pink dashed line.

360

361 **Discussion**

362 **Stem growth decoupled from iWUE variations**

363 Our study demonstrated that the paludification process considerably altered forest growth without,
 364 however, influencing the intrinsic water use efficiency of black spruce trees. Sites with the thickest
 365 organic matter accumulation were characterized by dominant trees that grew slower, presented
 366 smaller heights and diameters (DBH), and had a lower tree density comparatively to the least
 367 paludified site (Table 1; Fig. 3). These results are in agreement with previous studies that

368 documented forest productivity decline with increasing peat accumulation in the black spruce
369 feather moss domain of eastern Canada (e.g., Harper et al. 2003; Fenton et al. 2005; Lecomte et al.
370 2006; Simard et al. 2007). Surprisingly, however, our tree-ring stable isotope analysis indicates no
371 iWUE decrease over the last 100 years at the three study sites, but rather an important increase up
372 to the 1980s (Fig. 4a). Thus, contrary to our expectations, tree growth decline induced by the
373 paludification process does not result from a reduction in iWUE.

374

375 The stable isotope analysis revealed that $\delta^{13}\text{C}$ -derived parameters are almost identical in all sites
376 (no significant differences), both in terms of average iWUE levels and temporal variations,
377 suggesting that the ratio of assimilation rates to stomatal conductance is unaltered by the degree of
378 paludification. We thereby also refute our second research hypothesis. In order to maintain
379 comparable iWUE values across the paludification gradient (both in terms of mean and variability),
380 the proportionality of the A/g_s ratio needs to be preserved between sites. This implies that if A is
381 higher in the least paludified site (e.g., CAS0) and lower in the most paludified site (e.g., CAS100),
382 then g_s will adjust in such a way to maintain nearly identical A/g_s ratio, and consequently, iWUE
383 values. Actually, we suspect that this proportional adjustment in the A/g_s ratio might be an
384 important process driving interactions between iWUE and growth rates in a paludified context. As
385 a supporting evidence for this, we found that black spruce tree ring cellulose from the least
386 paludified site (CAS0) was significantly more depleted in ^{18}O compared to that of other sites (Fig.
387 4b). Unsurprisingly, CAS0 is also the site where radial growth rates are the highest. Increased
388 evapotranspiration rates are probably required to sustain enhanced carbon assimilation and growth
389 rates, forcing g_s to level up and proportionally adjust to increases in A (matching the ratio of other
390 sites). Consequently, higher evapotranspiration rates cause black spruce to pump more ^{18}O -depleted
391 water from soil depths (Evaristo et al. 2017), which in turn decreases the average $\delta^{18}\text{O}$ of tree ring
392 cellulose. Thus, the slower tree growth rates observed at the most paludified sites seem to result, at
393 least partially, from both lower carbon assimilation rates (A) and stomatal conductance (g_s).

394

395 These findings highlight that processes controlling radial tree growth are decoupled from those that
396 control gas exchanges (A and g_s), because of tree carbon use and allocation strategies. As an
397 example, many studies performed in non-paludified forests have shown that iWUE increases do
398 not directly translate into enhanced radial growth (e.g., Peñuelas et al. 2011; Lévesque et al. 2014;
399 van der Sleen et al. 2015; Giguère-Croteau et al. 2019). Based on a comparison of tree ring widths
400 and eddy-covariance flux towers in boreal Canada, Pappas et al. (2020) showed that aboveground
401 biomass, and most particularly radial stem growth, represents only a minor fraction (~9%) of the
402 total gross ecosystem production (GEP). Rocha et al. (2006) also found that stem growth, as
403 estimated from tree ring widths, was not correlated to eddy-covariance-derived GEP in the boreal
404 forest of central Manitoba. These findings point into the same direction: gas exchanges at the
405 vegetation-atmosphere interface are controlled at the leaf level, but the allocation of newly formed
406 photosynthates to either above or belowground compartments may depend on local growing
407 conditions and site-specific growth strategies. Our study must therefore be seen as an extreme case
408 where paludification induced locally-important edaphic changes that must have required tree
409 adaptation. Prioritization of belowground growth may have been more important in the most
410 paludified sites, neglecting carbon allocation to aboveground compartments. This allocation
411 strategy could reinforce tree anchoring (Nicoll et al. 2006) and enhance nutrient uptake (Vicca et
412 al. 2012; Fernández-Martínez et al. 2014), but further research is needed to shed light on the
413 processes driving allocation changes in black spruce trees.

414

415 **Synchronous changes in iWUE over time**

416 From the 1920s and until the 1980s, a ~40% iWUE increase was observed at each site, regardless
417 of the accumulated organic layer thickness. This important increase, which occurred over a short
418 period of time, is among the highest recorded; most studies report iWUE increases of 20-30% over

419 the last century (e.g., Peñuelas et al. 2011; Silva and Horwath 2013; Saurer et al. 2014; Frank et al.
420 2015; van der Sleen et al. 2015). The increased iWUE resulted from an active response of trees
421 characterized by the maintenance of a relatively constant c_i despite rising c_a .

422

423 Nevertheless, in the 1980s, tree response to rising c_a suddenly became passive, as shown by the
424 increasing c_i and the relatively constant c_a-c_i (iWUE) values at all sites (Fig. 4a). Likewise, a shift
425 to a passive response to increasing CO_2 concentration has previously been observed for various tree
426 species in the Canadian boreal forest (Giguère-Croteau et al. 2019; Marchand et al. 2020), in China
427 (Wang et al. 2012; Wu et al. 2015), and in Europe (Waterhouse et al. 2004; Gagen et al. 2011;
428 Linares and Camarero 2012). Three reasons might explain this shift in acclimation strategies.

429 Firstly, this finding possibly indicates reduced carbon assimilation rates (A). Indeed, in such poor
430 growing environments, the photosynthesis apparatus may saturate, and nutrient limitation may
431 downregulate the capacity of trees to assimilate atmospheric carbon (Tognetti et al. 2000; Saurer
432 et al. 2003). Secondly, WTD reconstructions indicate important changes in hydrological conditions
433 over the last 30 years (Fig. 5a) that might have altered black spruce iWUE. The recent water table
434 drawdown could have generated stressful growth conditions since black spruce develops
435 adventitious roots that are generally confined to the upper 20-30 cm of the organic layer (Liefers
436 and Rothwell 1987; Viereck and Johnson 1990). However, such a drop in WTD would have most
437 certainly been accompanied by a reduction in stomatal conductance over time, which was not
438 observed here. Moreover, the apparent drying trend could simply reflect an enhanced vertical
439 *Sphagnum* moss growth, promoted by increasing growing degree days in the last decades (Fig. 5b;
440 Magnan et al. 2018; van Bellen et al. 2018; Primeau and Garneau, accepted; Robitaille et al.
441 accepted). The rapid accumulation of organic matter may have exceeded the capacity of
442 adventitious roots to develop higher in the soil profile, compromising the access to oxygen. Lastly,
443 considering that black spruce trees were approximately 180 years old in the 1980s, we cannot rule

444 out the stand age as another potential cause for the reduction in iWUE (Irvine et al. 2004; Kutsch
445 et al. 2009; Marchand et al. 2020). Further studies are needed to determine which of these factors
446 is mainly responsible for the significant shift observed in tree ecophysiological strategies in the
447 1980s.

448

449 **Ecophysiological adjustments to changing conditions**

450 Site-specific conditions have resulted in different tree growth rates along the paludification
451 gradient. As mention above, our results suggest that tree growth decline induced by peat
452 accumulation is related to lower carbon assimilation rates (A) and stomatal conductance (g_s) in the
453 most paludified sites, but also potentially to prioritization of carbon allocation to belowground
454 components. Therefore, changes in local environmental conditions have led to tree
455 ecophysiological adaptations, particularly in the most paludified sites. However, these adjustments
456 in growth mechanisms do not show in tree iWUE. The ratio A to g_s did not differ between sites,
457 despite differences in peat thickness, water table depth, tree rooting depth, canopy cover, and tree
458 growth rates (Table 1, Figs. 3, S2.2). These results indicate that iWUE variations do not necessarily
459 reflect tree ecophysiological adjustments induced by changing growing conditions.

460

461 The significant apparent water table lowering in the early 2000s at the three sites (Fig. 5a) did not
462 induce any changes in iWUE. The diverging WTD trend starting around 1940 at CAS0 neither
463 translated into a diverging iWUE trend. Although some important environmental factors were not
464 investigated (e.g., nutrients, soil temperature), these results suggest that site-specific conditions
465 were not determinant in iWUE variations. The synchronous shift in iWUE at the three sites in the
466 mid-1980s rather points out to a response to regional or global conditions, which were experienced
467 by trees from all sites. Likewise, Pearson correlations calculated between standardized ring-width
468 series and climate variables (monthly temperature and precipitation) indicate a shift in tree response

469 to climate in the 1980s (SM 1.1; Fig. S2.8). Black spruce trees became much less sensitive to both
470 temperatures and precipitation after 1980. The reduced sensitivity of trees to temperature since the
471 mid-twentieth century has been reported in previous tree ring studies of northern high-latitude
472 forests, and has been referred to as the “divergence problem” (e.g., Briffa et al. 2004; D’Arrigo et
473 al. 2008; Esper and Frank 2009; Schneider et al. 2014). This “divergence” phenomenon could
474 potentially be caused by thresholded responses or stresses induced by changes in growth conditions
475 (D’Arrigo et al. 2008). While further studies are required to shed light on such trends, these
476 observations could support the hypothesis of photosynthesis apparatus saturation. Indeed,
477 photosynthetic capacity, stimulated by elevated CO₂ concentration, may have been limited by the
478 poor growing conditions of forested peatlands, thus stabilizing iWUE and inhibiting stem growth
479 response to temperature.

480

481 **Conclusions**

482 In this study, we investigated the mechanisms that are driving tree growth decline in black-spruce-
483 dominated forested peatlands of eastern Canada, by combining dendrochronological,
484 paleoecological, and dendrogeochemical analyses. We attempted, for the first time, to unravel the
485 numerous and complex entanglements between paludification dynamics and forest ecophysiology
486 in these boreal ecosystems. Contrary to our expectations, tree growth decline induced by the
487 paludification process does not result from a reduction of water use efficiency (iWUE). Indeed, we
488 observed no significant differences in iWUE variations between the three study sites, which
489 reflected different degrees of paludification. A substantial increase in iWUE was even recorded at
490 each site for more than 50 years. Our tree-ring stable isotope analyses suggest that the decline in
491 forest growth with increasing peat accumulation is rather explained by lower assimilation rates (A),
492 together with lower stomatal conductance (g_s), and possibly by the prioritization of carbon
493 allocation to belowground components. Moreover, we found no evidence of tree ecophysiological

494 adaptations to variations in water table depth. However, a significant shift in tree ecophysiology
495 observed in the 1980s at all sites may suggest that the ratio between assimilation rates and stomatal
496 conductance (iWUE) is influenced by regional or global factors, such as climate or increasing
497 atmospheric CO₂ concentration. These findings illustrate the complexity of the interactions
498 between stem growth, ecophysiological processes, and environmental conditions, particularly in
499 paludified sites. These dynamics will need to be further investigated to better predict the response
500 of boreal forested peatlands to future climate change.

501

502 Our findings warrant further studies of vegetation/forest dynamics models and their application to
503 forested peatlands, as those models are often biased towards converting increases in iWUE into
504 increases in stem growth. A successful modelling of the c_i/c_a ratio based on the least-cost optimality
505 principle (Lavergne et al. 2020) would predict comparable iWUE trends, with correct implications
506 for gas exchanges at the leaf level, regardless of the degree of paludification. However, failing to
507 account for paludification-related carbon use and allocation strategies would result in the
508 overestimation of aboveground biomass production in sites where peat accumulation is substantial.
509 Peatlands are one the largest natural terrestrial ecosystems for carbon sequestration, and forested
510 peatlands represent a major component of these ecosystems in boreal regions (Thompson et al.
511 2016; Webster et al. 2018). Therefore, additional research on carbon allocation strategies is of
512 utmost importance to understand the carbon sink capacity of black-spruce-dominated boreal
513 ecosystems and make appropriate forest management decisions.

514

515 **Declarations**

516 **Acknowledgements**

517 We are grateful to Dr. Pierre Grondin (MFFP, Québec) for his precious contribution to this project.

518 Thanks to Nolann Chaumont and Camille Lepage for their help with field and laboratory work.

519 Special thanks to Dr. Nicole Sanderson (Geotop, UQAM) for her help with ²¹⁰Pb dating. We also
520 thank *Les Tourbeux.ses* for their help and useful advice. Thanks to Dr. David Paré (Canadian Forest
521 Service, NRCan) and Dr. Nicolas Bélanger (Université TELUQ) for their comments on an earlier
522 version of the manuscript, and to two anonymous reviewers for their constructive comments that
523 greatly helped improving the manuscript.

524

525 **Authors' contributions**

526 All authors designed the research and conducted the fieldwork. J.B. performed the research and
527 É.B., M.G. and G.M. helped analyzing the data. J.B. wrote the first draft of the manuscript and all
528 authors contributed critically to subsequent drafts and gave final approval for publication.

529

530 **Funding**

531 Scholarships to J.B. were provided by the Natural Sciences and Engineering Research Council of
532 Canada (NSERC-CGS M) and the Fonds de recherche du Québec – Nature et technologies
533 (FRQNT). Fieldwork and analyses were funded by the Natural Sciences and Engineering Research
534 Council of Canada through discovery grants to M.G. and É.B.

Figures

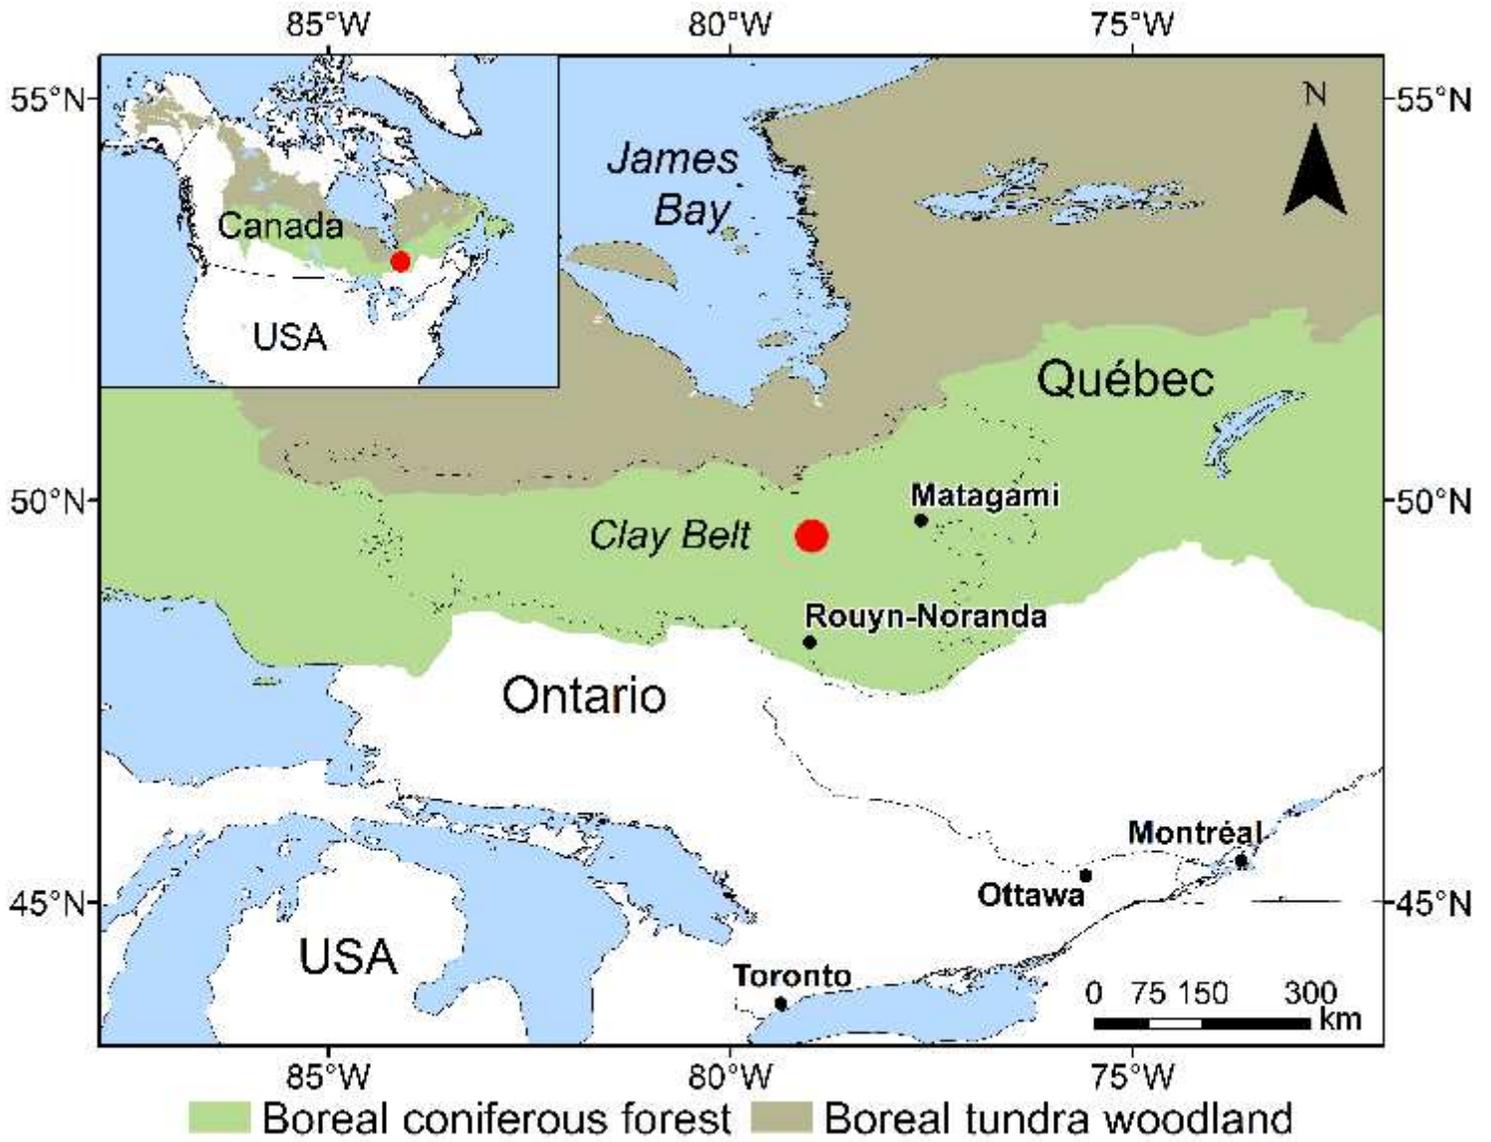

Figure 1

Location of the studied Casa boreal forested peatland (red dot).

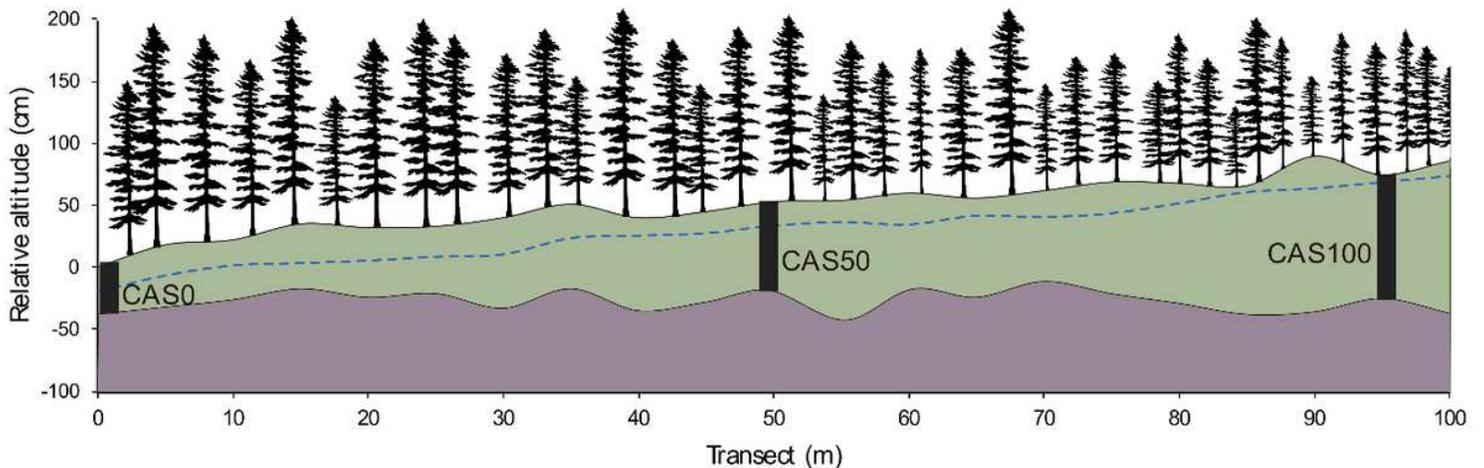

Figure 2

Schematic of the three sites along the study transect. Relative altitude of the organic layer (green) and the mineral surface (grey) are shown. Black rectangles represent the location of the sampled peat cores. The dotted blue line indicates the depth of the water table measured in the field. Trees are not to scale but are representative of variations in canopy openness along the transect.

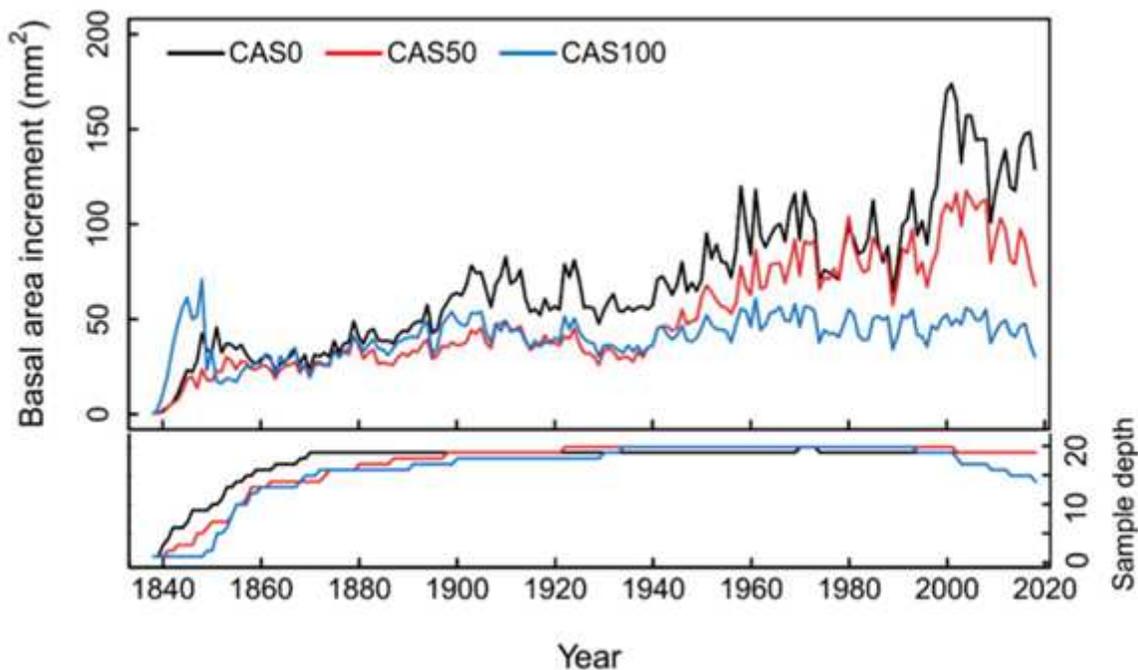

Figure 3

Mean annual basal area increment of black spruce trees since their establishment after the last fire event. The decrease in sample depth (n trees) at CAS100 since 2000 is explained by some trees for which the latest rings were partly absent. See Fig. S2.3 for BAI distribution.

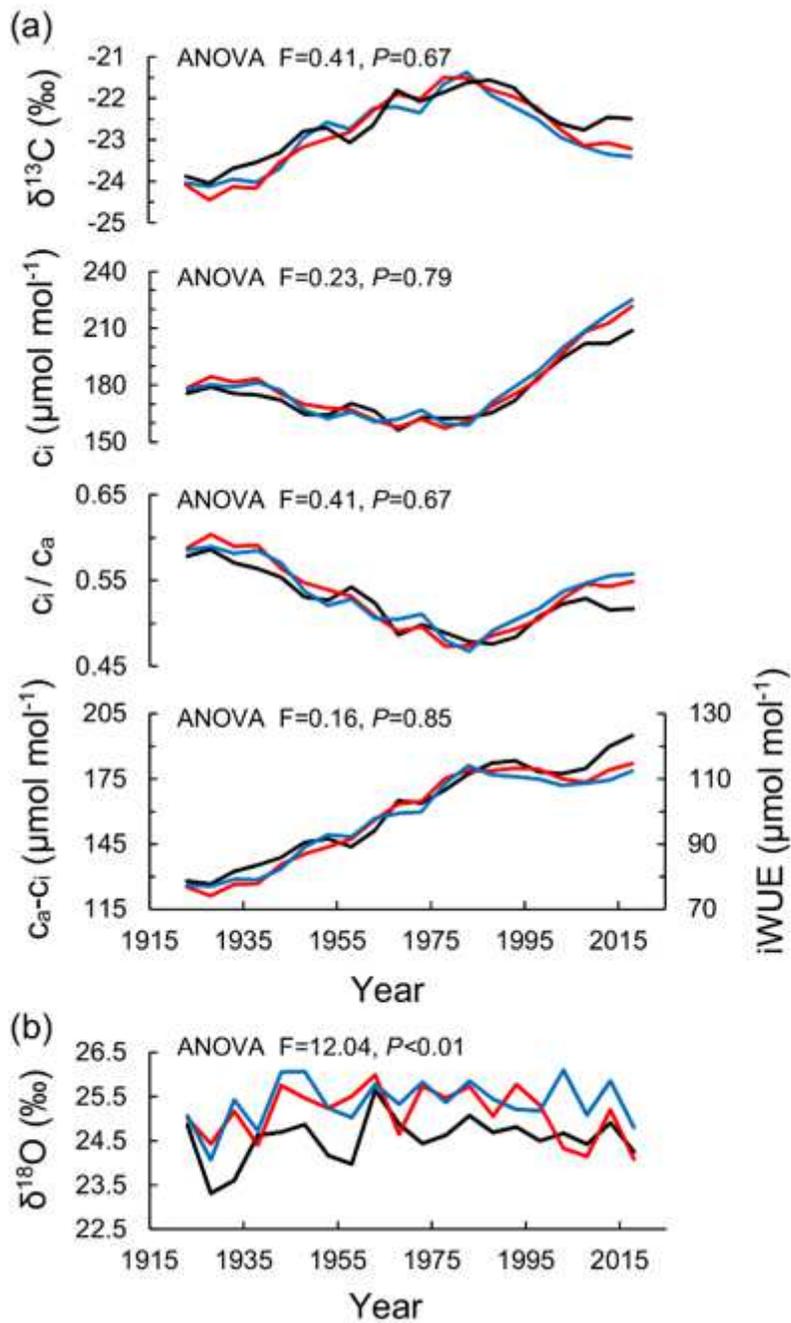

Figure 4

Black spruce ecophysiological response to rising $c\text{O}_2$ based on five-year resolution $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ analyses for the period 1919-2018. (a) Tree-ring $\delta^{13}\text{C}$ and $\delta^{13}\text{C}$ -derived ecophysiological parameter values (c_i , c_i / c_a , $c_a - c_i$, $i\text{WUE}$); (b) tree-ring $\delta^{18}\text{O}$ values. Results from CAS0, CAS50, and CAS100 are shown in black, red, and blue, respectively.

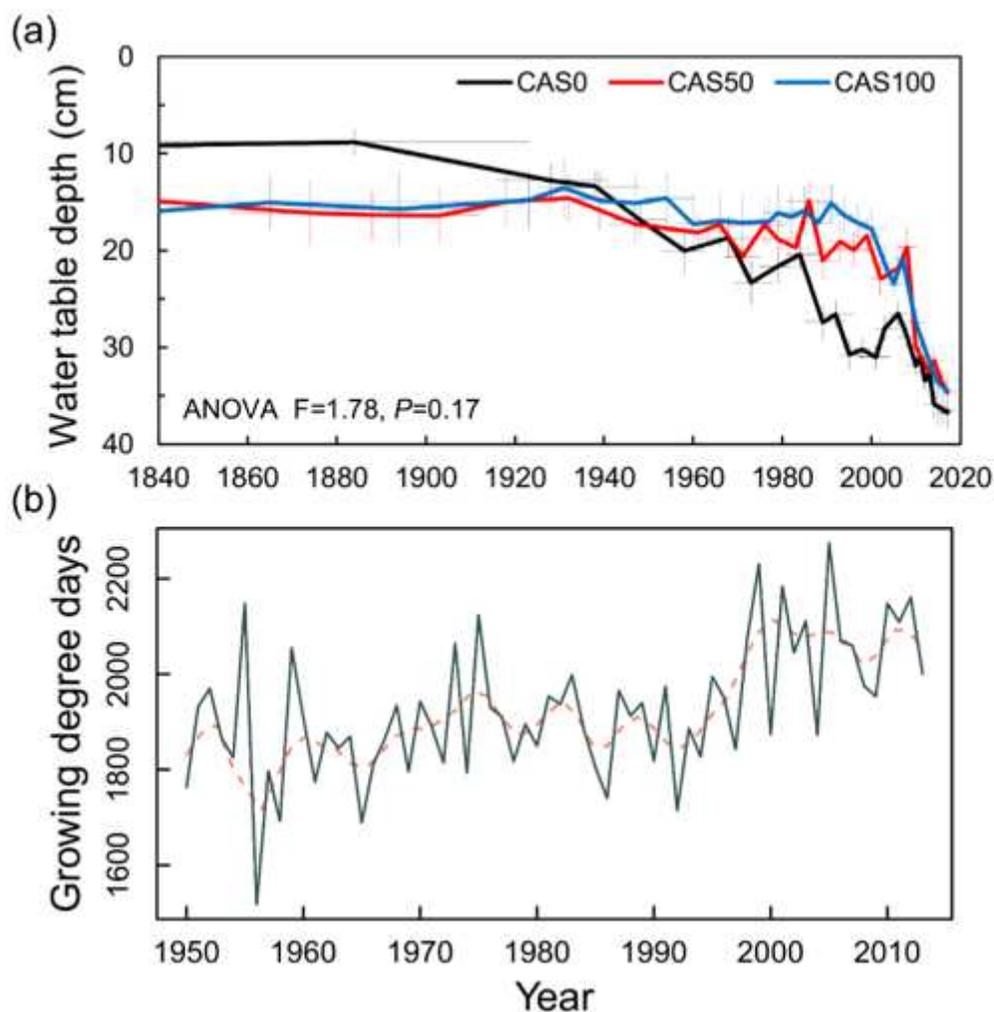

Figure 5

(a) WTD reconstructions for the post-fire period based on testate amoeba records and (b) growing degree days ($>0^{\circ}\text{C}$) from May to September in the study area for the period 1950-2013. Error bars of both WTD reconstructions and age-depth modelling are shown by pale thin lines. Climate data were extracted from McKenney et al. (2011). A 10-year loess smoothing is shown by the pink dashed line.
