13 **Abstract**

14 **Background:** Paludification is widespread in the boreal biome, inducing tree growth decline in
15 forested peatlands following the development of thick organic layers over the mineral soil.
16 However, the ecophysiological processes involved remain poorly documented and little is known
17 about the interactions between tree growth mechanisms and site conditions in these ecosystems.
18 We investigated changes in stem growth and main ecophysiological processes in a black spruce
19 forested peatland in eastern Canada by combining peat-based and tree-ring stable isotope analyses.
20 These were conducted at three sampling sites located along a paludification gradient with different
21 peat thicknesses.

22 **Results:** Organic layer thickening induces black spruce growth decline without altering tree
23 ecophysiological mechanisms. A 40% increase in water use efficiency, or the ratio of carbon
24 assimilated to water losses, was observed at the three sites from 1920 to the 1980s, but did not

25 translate into enhanced tree growth. A clear shift in the 1980s revealed a decline in black spruce
26 sensitivity to climate and rising atmospheric CO₂ concentration, regardless of the organic layer
27 thickness. Water table reconstructions revealed an important drawdown in the last few decades at
28 the three sites, but we found no evidence of an influence of water table variations on stem growth.

29 **Conclusions:** This study shows that paludification induces black spruce growth decline without
30 altering tree metabolism in boreal forested peatlands. This underlines that changes in water use
31 efficiency are decoupled from changes in carbon allocation, which are constrained by site, or even
32 tree-specific strategies to access water and nutrients from belowground. Our findings indicate that
33 dynamic changes in edaphic conditions need to be considered in process models. Otherwise, failing
34 to account for the degree of paludification can lead to misleading forest productivity predictions
35 and result in considerable overestimations of aboveground carbon stocks from trees in the boreal
36 regions.

37 **Keywords:** black spruce growth, boreal biome, climate-growth relationships, ecophysiological
38 response, forested peatland, paludification, stable isotopes, water use efficiency

39

40 **Background**

41 Forested peatlands are widespread ecosystems in the boreal regions of the Northern Hemisphere
42 that result from the paludification process (Korhola 1995; Crawford et al. 2003; Lavoie et al. 2005).
43 Northern forests are particularly prone to paludification due to their cold and humid climates,
44 particularly when combined with flat topography and fine-textured sediments (Payette 2001;
45 Charman 2002). This process is characterised by the development of thick organic layers over the
46 mineral sediment, favored by the establishment and expansion of *Sphagnum* mosses, which leads
47 to humid, acid, cold, and anaerobic soil conditions (Van Cleve et al. 1983; Fenton and Bergeron
48 2006). This edaphic context causes forest growth decline, primarily by limiting nutrient availability

49 (Van Cleve et al. 1983; Boudreault et al. 2002; Harper et al. 2003; Simard et al. 2007), and
50 eventually results in the establishment of open and/or forested peatlands. Over the past decades,
51 many studies have focused on documenting the effects of paludification on tree biomass
52 productivity (e.g., Lecomte et al. 2006; Simard et al. 2007, 2009) and developing management
53 practices to reduce or even reverse this process in coniferous boreal forests (e.g., Heikurainen 1964;
54 Lavoie et al. 2005; Bergeron et al. 2007; Fenton et al. 2009; Lafleur et al. 2011).

55

56 While the impacts of paludification on stem growth are well understood, forest ecophysiological
57 mechanisms associated with growth decline remain unknown at the stand scale. In non-paludified
58 forests, an increase in tree intrinsic water use efficiency (i.e., the ratio of carbon assimilated to
59 water losses through evapotranspiration; Farquhar et al. 1989) associated with rising ambient CO₂
60 concentration has commonly been reported without enhancing carbon use efficiency (Manzoni et
61 al. 2018) or tree radial growth (e.g., Peñuelas et al. 2011; Silva and Horwath 2013; Lévesque et al.
62 2014). Indeed, while photosynthesis stimulation and stomatal conductance reduction control
63 changes in water use efficiency, stem growth appears to be limited by local edaphic factors, such
64 as nutrient availability (e.g., nitrogen). Paludification is thus expected to alter both water and carbon
65 use efficiency in boreal forested peatlands, given that this process induces significant changes in
66 soil conditions.

67

68 Both vegetation and hydrological dynamics in paludified settings have previously been studied
69 over millennial timescales (Ruppel et al. 2013; Le Stum-Boivin et al. 2019; Magnan et al. 2019).
70 Nonetheless, little is known about the implications of changes in ecosystem conditions on tree
71 growth mechanisms in forested peatlands. Paludification is characterized by water table rise
72 (Lavoie et al. 2005; Fenton and Bergeron 2006), and interactions over time may indeed exist
73 between water table fluctuations, tree nutrition, and stem growth responses in boreal ecosystems.
74 These interactions may influence the respective contribution of ecophysiological processes such as

75 photosynthesis and stomatal conductance, which control tree water use efficiency. Enhanced
76 knowledge of forested peatland ecophysiology may ultimately improve the modelling of the
77 response of these ecosystems to increasing CO₂ concentrations by dynamic global vegetation
78 models (DGVMs) (Pugh et al. 2016).

79

80 In this study, we aim to improve the understanding of the mechanisms that support tree radial
81 growth in black spruce (*Picea mariana* (Mill.) BSP)-forested peatlands of eastern Canada, using
82 an innovative approach that combines multi-proxy analyses. Peat-based paleoecohydrological
83 analyses were performed in parallel with stable isotope analyses in tree rings to investigate the
84 interactions between black spruce metabolism and site conditions. We hypothesise that peat
85 accumulation triggers changes in tree ecophysiological mechanisms (e.g., reduction in
86 photosynthesis rates) which result in stem growth decline. We expect this effect to be stronger in
87 the most paludified sites characterised by thicker peat deposits.

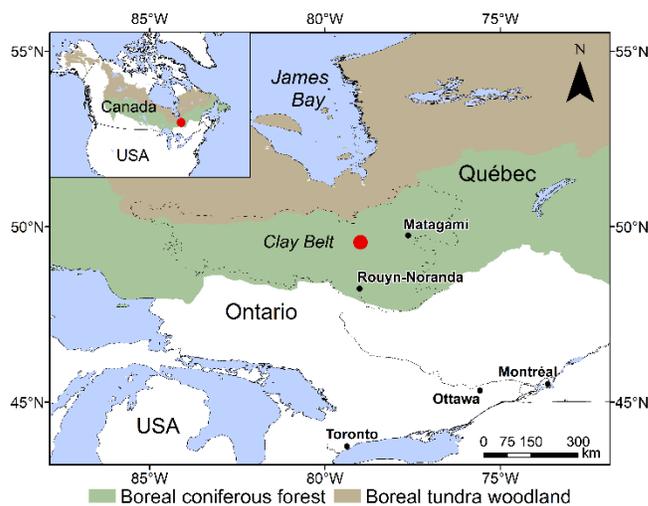

88

89 **Methods**

90 **Study area**

91 The study was conducted south of James Bay in eastern Canada, within the Clay Belt region part
92 of the black spruce-feather moss bioclimatic domain (Saucier et al. 2009; Fig. 1). This area is
93 particularly prone to paludification due to the relatively cold and humid climate, the flat
94 topography, and the dominance of poorly-drained clayey sediments left by the proglacial lakes
95 Barlow and Ojibway (Vincent and Hardy 1977; Fenton et al. 2005; Lavoie et al. 2005). Mean
96 annual temperature is 0.3°C (over the 1950-2013 period), ranging from -18.9°C in January to
97 16.3°C in July, and mean annual precipitation is 818 mm (McKenney et al. 2011). The regional fire
98 cycle is estimated to be ~400 years since 1920 (Bergeron et al. 2004), allowing the accumulation
99 of thick organic layers in forests between fire events.

100 The Casa forested peatland (49°33'06"N, 78°59'10"O; Fig. S2.1) was selected following the studies
101 of Magnan et al. (2020) and Le Stum-Boivin et al. (2019) due to its regional representativeness in
102 terms of slope, vegetation composition, and canopy openness. The organic layer thickness varies
103 between 40 cm and more than 1 m along the selected transect, and the canopy gradually opens with
104 organic layer thickening, which is typically observed in forested peatlands of the Clay Belt. The
105 aboveground vegetation is largely dominated by black spruce and ericaceous shrubs, such as
106 *Vaccinium angustifolium*, *Rhododendron groenlandicum*, *Kalmia angustifolia*, and
107 *Chamaedaphne calyculata*. The understory is dominated by *Sphagnum* communities, particularly
108 *S. angustifolium/fallax* under the tree canopy, and *S. fuscum* where the tree canopy is more open.
109

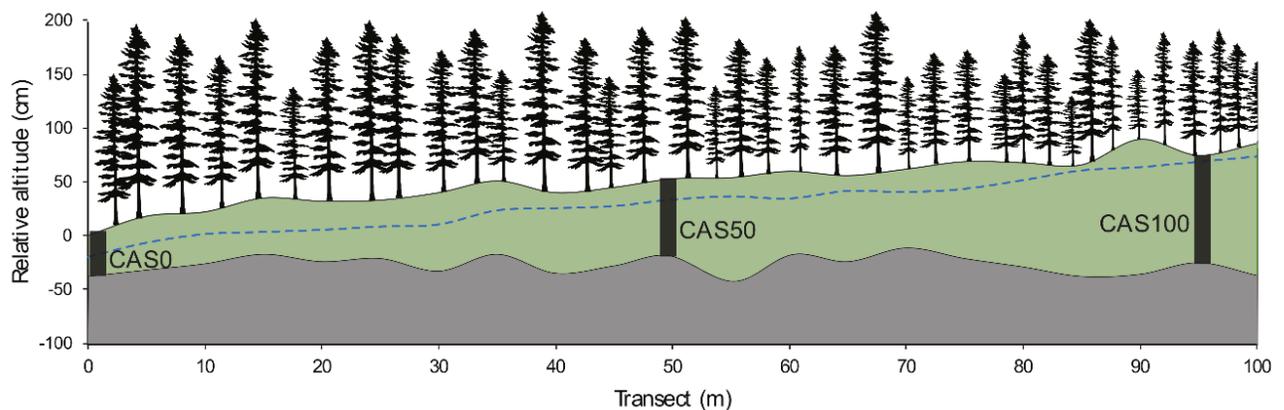

110
111 **Figure 1. Location of the studied Casa boreal forested peatland (red dot).**

112

113 **Sampling**

114 Three sampling sites (CAS0, CAS50, CAS100) were established along a 100 m transect following
115 an organic matter thickness gradient within the selected forested peatland (Fig. 2). At each site, one
116 peat monolith was sampled down to the mineral contact using a Box corer (Jeglum et al. 1992).
117 Sampling locations were chosen to be representative of the mean peat thickness of each site.

118 Relative surface altitude and peat thickness were measured at 5 m intervals along the transect using
119 a high precision altimeter (ZIPLEVEL PRO-2000) and an Oakfield probe. Water table depths were
120 measured at the same intervals a few hours after holes were dug to make sure that the water table
121 level had stabilized. Twenty black spruce trees were also sampled at each site within a 10 m radius
122 of the collected peat core. Only dominant and codominant trees with straight stems and no visible
123 scars were selected. Peat thickness was measured at the bottom of each sampled tree to validate the
124 concordance with the mean peat thickness of the site. The diameter at breast height (DBH) and the
125 height of selected trees were measured and cross-sections were collected at standard height (1.3 m).
126 The root system of one black spruce per site was excavated to verify the depth of the rooting zone,
127 and to identify the growth substrate (i.e., mineral or organic matter). Moreover, tree aboveground
128 biomass of each site was estimated by measuring the diameter at breast height (DBH) of all trees
129 (DBH \geq 1 cm) within a 10 \times 10 m plot and then using allometric equations adapted to black spruce
130 growth (Lambert et al. 2005; Ung et al. 2008).
131

132
133 **Figure 2. Schematic of the three sites along the study transect.** Relative altitude of the organic
134 layer (green) and the mineral surface (grey) are shown. Black rectangles represent the locations of
135 the sampled peat cores. The dotted blue line indicates the water table level measured on the field.
136 Trees are not to scale but are representative of variations in canopy openness along the transect.
137

138 **Peat-based paleoecohydrological reconstructions**

139 Prior to analysis, peat cores were cut into 1 cm-thick slices. Plant macrofossils were analysed at 4
140 cm intervals along each peat core to reconstruct vegetation dynamics since peat initiation. Samples
141 were prepared following the standard protocol of Mauquoy et al. (2010) and analysed in a gridded
142 Petri dish under a stereoscopic microscope (10-40 × magnification) (SM 1.1). The relative
143 abundances of the main peat components (e.g., *Sphagnum*, ligneous, Cyperaceae) were estimated
144 visually and expressed as volume percentages, and vascular plant remains (e.g., seeds, needles,
145 leaves) were counted. Macroscopic charcoal particles (>0.5 mm) were analysed at 1 cm intervals
146 along the three peat cores to identify past local fire events.

147

148 In order to reconstruct hydrological variations, testate amoeba assemblages were also analysed at
149 1 cm intervals. Testate amoeba shells were extracted following the standard protocol of Booth et
150 al. (2010) (SM 1.2). Samples were then analysed under an optical microscope (400×
151 magnification). A minimum of 100 tests was counted per sample, except in highly humified peat
152 samples, in which test concentration was very low. In these cases, no water table depth (WTD) was
153 inferred, as the total count (< 20 tests) was insufficient to ensure reliable WTD reconstruction
154 (Payne and Mitchell 2009).

155

156 Past WTDs were reconstructed using a weighted average model with tolerance down-weighting
157 and inverse deshrinking (WA.inv.tol). The transfer function was built using the R package *rioja*
158 (version 0.9-15.1; Juggins 2017), from a modern dataset of 272 surface samples combining non-
159 forested open peatlands (Lamarre et al. 2013) and forested peatlands (Beaulne et al. 2018 and this
160 study) of eastern Canada. High inferred WTD values corresponded to drier surface conditions.

161

162

163 **Peat core chronologies**

164 A total of 11 samples were submitted to A. E. Lalonde AMS Laboratory (University of Ottawa,
165 Canada) for accelerator mass spectrometry radiocarbon dating (^{14}C). Plant macrofossil remains
166 were carefully selected to date peat initiation, the last fire event, and main transitions in vegetation
167 composition at each sampling site. The ^{14}C dates were calibrated using the IntCal13 calibration
168 curve (Reimer et al. 2013). Additional ^{210}Pb dating was achieved for the uppermost 24-26 cm of
169 peat cores at 1 cm intervals by alpha spectrometry (EGG Ortec 476A) at the GEOTOP Research
170 Center (Université du Québec à Montréal, Canada). Ages were inferred by ^{210}Po activity
171 measurement, using the constant rate of supply model (Appleby and Oldfield 1978) following
172 $\text{HNO}_3\text{-HCl-H}_2\text{O}_2$ sample digestion. Further details on the ^{210}Pb dating procedure used in this study
173 can be found in Ali et al. (2008). Age-depth models were generated using the *rbacon* package in R
174 (version 2.3.9.1; Blaauw and Christen 2019). Ages are expressed in calendar years before present
175 (cal yr BP; 1950 CE) and the age of the peat surface is therefore set to -67 cal yr BP (coring year:
176 2017 CE).

177

178 **Black spruce radial growth analysis**

179 Dried cross-sections were finely sanded (from 80 to 600 grit size) prior to ring-width measurements
180 along two radii using CooRecorder software (version 8.1.1; Cybis Elektronik & Data AB 2016).
181 Samples were visually cross-dated using PAST5 software (version 5.0.610; SCIEM 2019), and
182 skeleton plots were generated using the R package *dplR* (version 1.6.9; Bunn et al. 2018). Ring-
183 width series were converted to annual basal area increment (BAI) to compare tree aboveground
184 productivity between the three sites, as BAI is more representative of three-dimensional stem
185 growth than the linear ring-width measurements (Husch et al. 2003; Biondi and Qeadan 2008).
186 Individual BAI series were produced using the R package *dplR* (version 1.6.9; Bunn et al. 2018),
187 and yearly averages were then calculated using all trees from the same site.

188 Ring-width series were standardized using a negative exponential curve to remove cambial age
189 trends (Fritts 1976). Standardization was performed on all individual series before constructing a
190 mean standardized chronology for each site. Daily climate data (mean temperature and total
191 precipitation) from 1950 to 2013 were retrieved from the interpolated gridded climate dataset of
192 McKenney et al. (2011). Pearson correlation coefficients were calculated between standardized
193 ring-width series and monthly climate data from March to September of both the current year and
194 the year preceding ring formation. Because of time series autocorrelation, effective numbers of
195 degrees of freedom were calculated to generate adjusted *p*-values (Hu et al. 2017).

196

197 **Isotopic analysis of tree rings**

198 Black spruce ecophysiological response to rising ambient CO₂ concentration and climate variability
199 was evaluated from carbon ($\delta^{13}\text{C}$) and oxygen ($\delta^{18}\text{O}$) isotopic ratio analyses. These were performed
200 on five trees per site and from two wood strips per tree (i.e., a total of 30 samples). Sample
201 preparation was carried out following the protocol described in Giguère-Croteau et al. (2019) (SM
202 1.3). A five-year resolution over a 100 year period (1919-2018) was considered. Alpha-cellulose
203 was extracted, as suggested for black spruce samples (Bégin et al. 2015), following the protocol
204 used by Naulier et al. (2014).

205

206 Tree-ring $\delta^{13}\text{C}$ values vary according to discrimination against ^{13}C during photosynthesis, defined
207 as (Farquhar et al. 1982):

208

$$209 \quad \Delta^{13}\text{C} = \frac{\delta^{13}\text{C}_{\text{air}} - \delta^{13}\text{C}_{\text{tree}}}{1 + (\delta^{13}\text{C}_{\text{tree}}/1000)}, \quad (1)$$

210 where $\delta^{13}\text{C}_{\text{air}}$ is the carbon isotope ratio of the atmosphere and $\delta^{13}\text{C}_{\text{tree}}$ is the isotopic value of the
211 tree ring. $\delta^{13}\text{C}_{\text{air}}$ values were taken from McCarroll and Loader (2004) for the 1919-2003 period,

212 and were linearly extrapolated for the 2004-2018 period. Because of the five-year resolution of
213 $\delta^{13}\text{C}_{\text{tree}}$ values, we averaged the $\delta^{13}\text{C}_{\text{air}}$ values over five years. According to Farquhar et al. (1989),
214 $\Delta^{13}\text{C}$ is related to leaf intercellular CO_2 concentration (c_i) and ambient CO_2 concentration (c_a)
215 according to the following equation:

216

$$217 \quad \Delta^{13}\text{C} = a + (b - a) \left(\frac{c_i}{c_a} \right), \quad (2)$$

218 where a (4.4‰) is the fractionation occurring during CO_2 diffusion through stomata (O’Leary
219 1981) and b (27‰) is the fractionation due to carboxylation by the Rubisco enzyme (Farquhar and
220 Richards 1984). Values of c_a were obtained from the Mauna Loa Observatory
221 (esrl.noaa.gov/gmd/ccgg/). Intrinsic water use efficiency (iWUE), defined as the amount of carbon
222 assimilated per unit of water lost, can then be estimated from c_i and c_a as follows (Ehleringer et al.
223 1993):

224

$$225 \quad \text{iWUE} = \left(\frac{A}{g_s} \right) = \left(\frac{c_a - c_i}{1.6} \right), \quad (3)$$

226 where A is the rate of CO_2 assimilation, g_s is the stomatal conductance, and the constant 1.6
227 represents the ratio of water vapor and CO_2 diffusivity in air. Equation 3 shows that the difference
228 between c_a and c_i is related to the ratio of assimilation (A) to stomatal conductance (g_s).

229

230 Since the $\delta^{18}\text{O}$ composition of tree rings is mainly controlled by leaf water composition and
231 enrichment due to transpiration of lighter oxygen isotopes, $\delta^{18}\text{O}$ values are assumed to be related
232 to the stomatal conductance and independent of photosynthetic activity (Yakir 1992; Barbour
233 2007). Therefore, by combining $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ analyses it is possible to discriminate the effects of
234 changes in photosynthetic rate (A) and stomatal behavior (g_s) on iWUE (Scheidegger et al. 2000).

235 Results

236 Paleocohydrological reconstructions

237 The study sites CAS0, CAS50, and CAS100 have an organic layer thickness of 40, 75, and 100 cm
238 respectively (Table 1). Tree-ring analyses revealed even-aged stands covering the period 1839-
239 2018 CE at each site (see sample depth in Fig. 4 for tree age variability). Radiocarbon dating of the
240 most recent charcoal layer indicates that the last fire event occurred between 0 and 290 cal yr BP
241 (median age: 175-179 cal yr BP; Table S2.1). These results suggest that trees were from the first
242 cohort that grew after the last local fire, which most likely occurred around 200-250 years ago
243 (~1800 CE). The depth of the uppermost charcoal layer in the peat profile indicates that black
244 spruce established in a residual organic layer of 15, 45, and 65 cm at sites CAS0, CAS50, and
245 CAS100 respectively. The root system excavation of the three selected trees suggests that roots
246 reached the mineral soil at CAS0 and CAS50, but were restricted to the organic layer at CAS100.

247

248 **Table 1. Characteristics of the three study sites.**

Site	Organic layer thickness (cm)	WTD (cm)	Mean DBH (cm)	Trees (<i>n</i>)	Tree biomass (kg m ⁻²)	Tree density ^a (trees ha ⁻¹)	Mean tree height ^b (m)
CAS0	40	25	10.4	20	8.9	1200	13.8
CAS50	75	19	9.4	24	7.6	1200	11.3
CAS100	100	10	5.6	34	4.6	1000	10.4

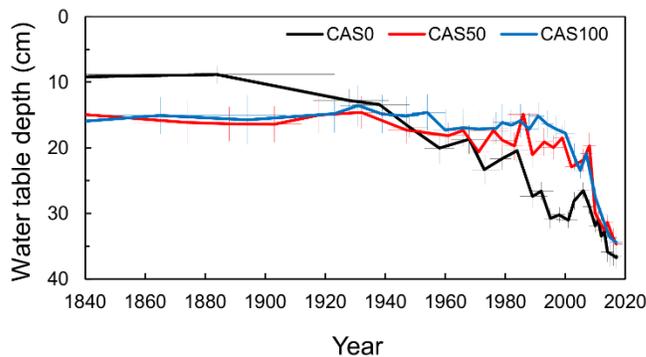

249 ^a Include trees with a diameter at breast height (DBH) ≥ 9 cm

250 ^b Calculated from the twenty black spruce trees (dominant and co-dominant) sampled at each site.

251

252 Both hydrological conditions and vegetation composition were similar across the three sites
253 throughout the duration of black spruce growth (Fig. S2.2, S2.3). Macrofossil analysis showed that
254 the last fire induced a shift in vegetation composition from high dominance of woody vegetation to
255 a black spruce-*Sphagnum*-dominated stand (Fig. S2.2). The canopy opening allowed rapid

256 *Sphagnum* moss expansion in the bryophyte layer while the black spruce post-fire cohort
257 established. Testate amoeba records indicate relatively wet conditions (high water tables) shortly
258 after the fire, followed by a gradual lowering of the water table at the three sites (Fig. 3, S2.3).
259 Inferred WTD values show very similar hydrological conditions at CAS50 and CAS100 during the
260 post-fire period (1840-2017). Both sites had stable water table depths between 15 and 20 cm before
261 water tables deepened from the 1990s, and particularly in the very recent horizons (~2010), while
262 the water table lowered more gradually at CAS0.
263

264
265 **Figure 3. WTD reconstructions for the post-fire period based on testate amoeba records.** Error
266 bars of both WTD reconstructions and age-depth modelling are shown by pale thin lines.

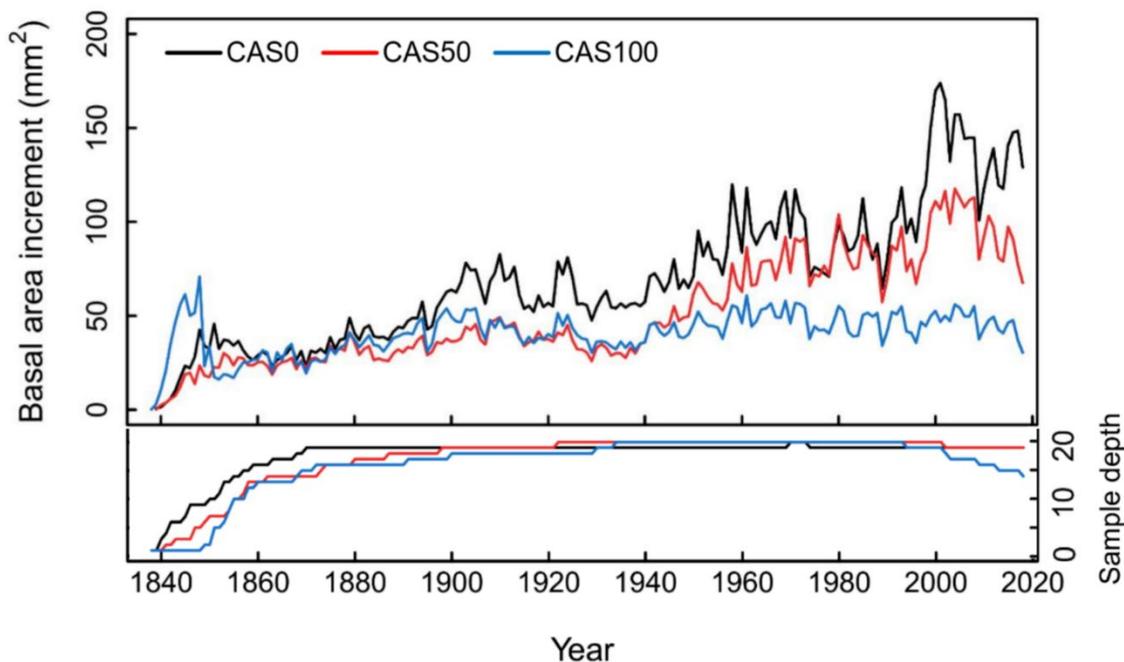

267

268 **Black spruce radial growth**

269 A decrease in DBH and tree height values was observed in relation with organic layer thickening
270 along the paludification gradient (Table 1). Mean DBHs of 10.4, 9.4, and 5.6 cm were calculated
271 for CAS0, CAS50, and CAS100 respectively. BAIs also indicate a decrease in stem growth with
272 increasing peat thickness (Fig. 4, S2.4). Trees from CAS0 added a greater wood surface with age,
273 especially since 1940, resulting in an increasing BAI trend (mean BAI=70 mm²). At CAS50, tree
274 radial growth was more limited (mean BAI=51 mm²). In contrast, trees from CAS100 maintained
275 relatively constant BAI values, resulting in decreased wood production (mean BAI=40 mm²).

276 Estimates of tree aboveground biomass showed similar trends with values of 8.9, 7.6, and 4.6 kg/m²
277 for sites CAS0, CAS50, and CAS100 respectively.

278

279

280 **Figure 4. Mean annual basal area increment of black spruce trees since their establishment**
281 **after the last fire event.** The decrease in sample depth at CAS100 since 2000 is explained by some
282 trees for which the latest rings were partly absent. See Fig. S2.4 for BAI distribution.

283

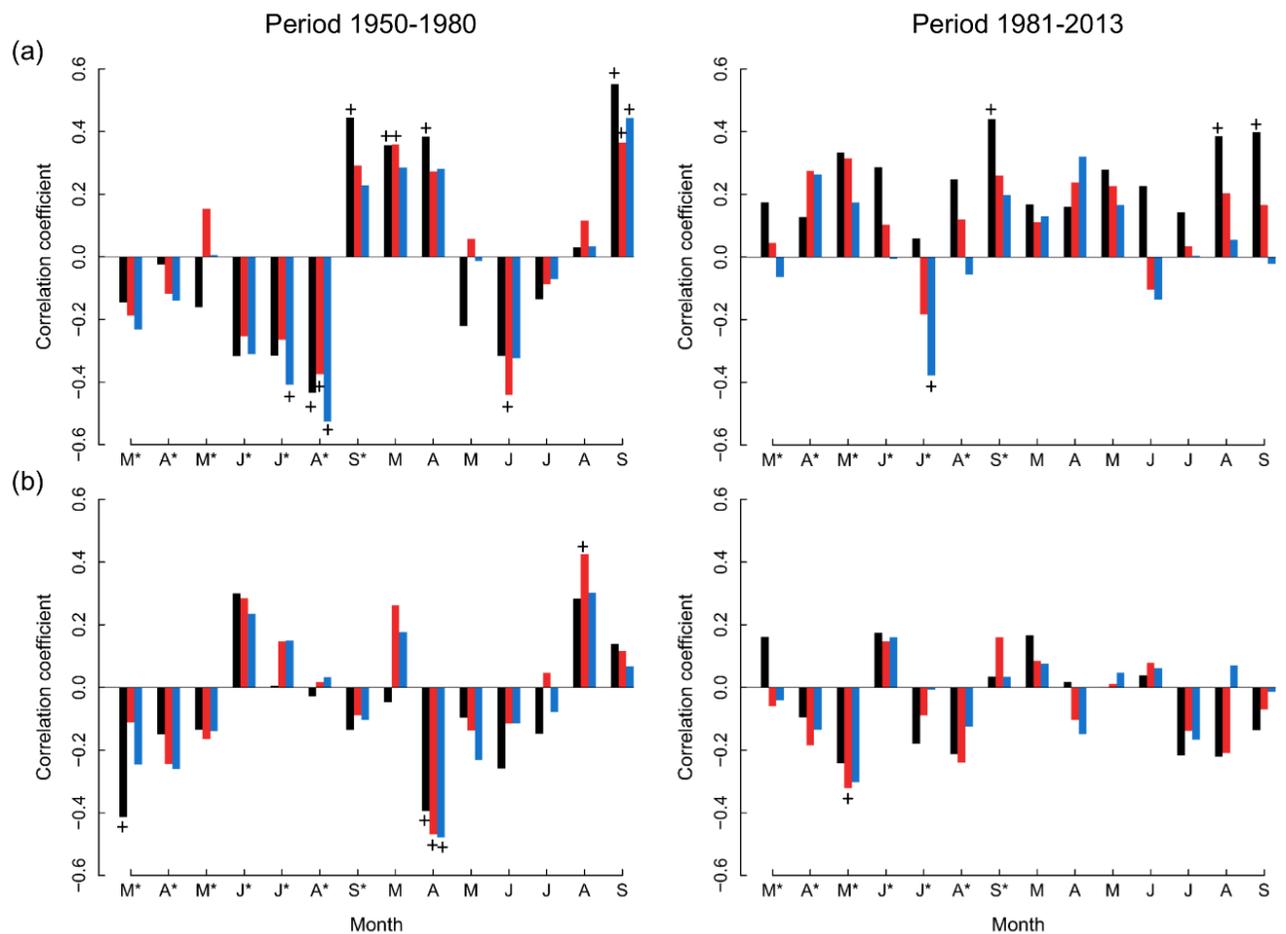

284 **Stem growth response to climate**

285 Pearson correlations between standardized ring-width series (Fig. S2.5) and monthly temperature
286 and precipitation data were performed separately for the 1950-1980 and 1981-2013 periods. These
287 two time periods were chosen because of the shift in black spruce ecophysiology around 1980 (see
288 next section) and the results of moving correlations with climate variables (results not shown).

289

290 Temperature's influence on tree radial growth was stronger than that of precipitation for both time
291 periods. Trees had a similar response to climate at all sites for the period 1950-1980 (Fig. 5). For

292 all sites, negative correlations were observed between tree stem growth and both temperature of
 293 the previous August and April precipitation of the current year. Stem growth was also positively
 294 correlated with September temperature of the current year. Contrastingly, stem growth barely
 295 responded to climate during the 1981-2013 period, with much less significant and rather
 296 heterogeneous correlations at the three sites (Fig. 5).
 297

298
 299 **Figure 5. Pearson correlations between (a) standardized ring-width and monthly**
 300 **temperature, and (b) standardized ring-width and monthly precipitation for the periods**
 301 **1950-1980 and 1981-2013.** Correlation coefficients were calculated from March to September of
 302 the current year and the year preceding ring formation. Months from the previous year of stem

303 growth are marked with an asterisk and significant correlations ($p < 0.05$) are marked with crosses.

304 Results from CAS0, CAS50, and CAS100 are shown in black, red, and blue respectively.

305

306 **Trends in $\delta^{13}\text{C}$, $\delta^{18}\text{O}$, and iWUE**

307 The $\delta^{13}\text{C}$ -derived ecophysiological parameters do not differ between the three sites over the 1919-

308 2000 period (Fig. 6a). Over time, black spruce trees used two different strategies in response to

309 rising c_a . A substantial increase in iWUE was first observed until the 1980s ($c_a \approx 340$ ppm), along

310 with relatively stable intercellular CO_2 concentration (c_i). During this period, iWUE increased by

311 43% at each site. A major shift in tree ecophysiology then occurred in the mid-1980s as c_i began to

312 increase considerably. In parallel, iWUE stabilized until 2018, except for at CAS0, where a new

313 increase seems to have begun around 2000.

314

315 Tree-ring cellulose $\delta^{18}\text{O}$ analyses show similar trends for the three sites across the whole record

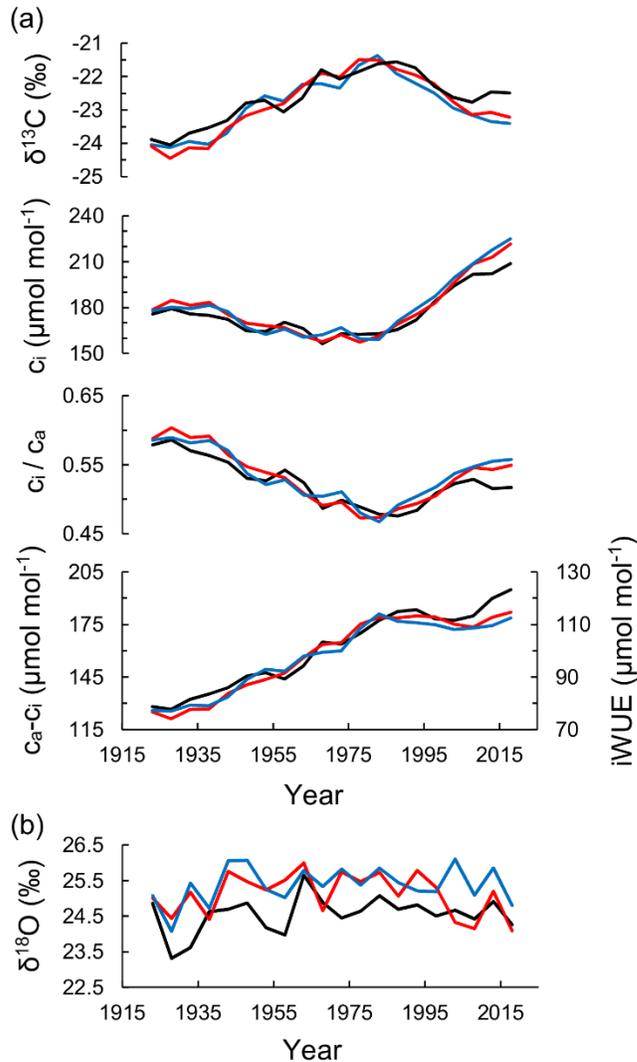

316 (Fig. 6b). However, oxygen stable isotope ratios were systematically lower at the least paludified

317 site (CAS0), suggesting a greater depletion in heavy isotopes. For all series, tree-ring $\delta^{18}\text{O}$ values

318 increased until ~ 1950 and became more constant afterwards.

319

326

327 Discussion

328 Our study demonstrated that the degree of paludification considerably altered growth conditions

329 and site fertility, but did not influence intrinsic water use efficiency of black spruce trees. Indeed,

330 sites with the thickest organic matter accumulation were characterized by dominant trees that grew

331 slower, presented smaller heights and diameters (DBH), and had a lower tree density comparatively
332 to the least paludified site (Table 1). Surprisingly, however, $\delta^{13}\text{C}$ -derived parameters are almost
333 identical in all sites (Fig. 6), both in terms of average iWUE levels or temporal variations,
334 suggesting that the ratio of photosynthesis to stomatal conductance is unaltered by the degree of
335 paludification. We therefore refute our research hypothesis, and cannot ascertain a clear and direct
336 effect of increased peat accumulation on black spruce water use efficiency and growth mechanisms.

337

338 Site fertility was recently put forward as an important parameter influencing black spruce iWUE
339 and its evolution with changes in c_a (Marchand et al. 2020). Based on a network of permanent
340 sampling plots in eastern Canada, average iWUE values were shown to be lower in the most fertile
341 sites (i.e., fertility being measured based on tree heights for equivalent age). Fertile sites also
342 experienced the most drastic iWUE increase with rising c_a , while this increase remained modest in
343 the least fertile sites. However, in their study, Marchand et al. (2020) examined only sites where
344 organic matter accumulation was inferior to 30 cm. Along our paludification gradient, peat
345 thickness reaches about 100 cm at CAS100 and therefore other processes linking organic matter
346 accumulation, water table depth, and climate need to be invoked in order to shed light on
347 interactions between iWUE and radial growth of black spruce in a paludified context.

348

349 **Synchronous changes in iWUE over time**

350 *1920-1980s: iWUE increases (active response)*

351 From the 1920s and until the 1980s, a ~40% iWUE increase was observed at each site, regardless
352 of the accumulated organic layer thickness. This significant increase, which occurred over a short
353 period of time, is among the highest recorded; most studies report iWUE increases of 20-30% over
354 the last century (e.g., Peñuelas et al. 2011; Silva and Horwath 2013; Saurer et al. 2014; Frank et al.
355 2015; van der Sleen et al. 2015). The increased iWUE resulted from an active response of trees

356 characterized by the maintenance of a relatively constant c_i despite rising c_a . According to
357 Scheidegger et al. (2000), when both $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values increase, as subtly observed here until
358 the 1950s (Fig. 6), stomatal conductance most likely is the main driver of increased $i\text{WUE}$ since it
359 is involved in the fractionation of both stable isotopes. Stomatal closure was possibly induced by
360 the combined effect of rising c_a and severe drought events that took place in the study area at the
361 beginning of the twentieth century (Girardin et al. 2004). This reduction in stomatal conductance
362 could have limited growth during the 1920-1950s period, leading to the formation of smaller and
363 narrower cells (Puchi et al. 2020; Fig. 4, S2.5). After 1950 and until the 1980s, $\delta^{13}\text{C}$ values
364 continued to increase, whereas $\delta^{18}\text{O}$ values remained relatively constant. This points to a shift in
365 acclimation strategies from a g_s -controlled $i\text{WUE}$ to an A -controlled increase in $i\text{WUE}$, maintaining
366 c_i values constant.

367

368 *1980s-2010s: iWUE stabilises (passive response)*

369 In the 1980s, tree response to rising c_a suddenly became passive, as shown by the increasing c_i and
370 the relatively constant c_a - c_i ($i\text{WUE}$) values at all sites (Fig. 6). Likewise, a shift to a passive
371 response to increasing CO_2 concentration has previously been observed for various tree species in
372 the Canadian boreal forest (Giguère-Croteau et al. 2019; Marchand et al. 2020), in China (Wang et
373 al. 2012; Wu et al. 2015), and in Europe (Waterhouse et al. 2004; Gagen et al. 2011; Linares and
374 Camarero 2012). Three reasons might explain this shift in acclimation strategies. Firstly, this
375 finding possibly indicates reduced carbon assimilation rates (A). Indeed, in such poor growing
376 environments, the photosynthesis apparatus may saturate and nutrient limitation may downregulate
377 the capacity of trees to assimilate atmospheric carbon (Tognetti et al. 2000; Saurer et al. 2003).
378 Secondly, WTD reconstructions indicate important changes in hydrological conditions over the last
379 30 years (Fig. 3) that might have altered black spruce $i\text{WUE}$. The recent water table drawdown
380 could have generated stressful growth conditions since black spruce develops adventitious roots

381 that are generally confined to the upper 20-30 cm of the organic layer (Lieffers and Rothwell 1987;
382 Viereck and Johnson 1990). However, such a drop in WTD would have most certainly been
383 accompanied by a reduction in stomatal conductance, which was not observed here. Moreover, it
384 remains unclear whether the apparent drying trend reflects increasingly drier site conditions or
385 simply an enhanced vertical *Sphagnum* mosses growth that disconnects the peat surface from the
386 water table. Increasingly warmer conditions since the 1990s (Fig. S2.6) could have triggered this
387 rapid peat accumulation (Magnan et al. 2018; van Bellen et al. 2018; Primeau and Garneau, under
388 review; Robitaille et al. submitted). The rapid accumulation of organic matter may have exceeded
389 the capacity of adventitious roots to develop higher in the soil profile, compromising the access to
390 oxygen. Lastly, considering that black spruce trees were approximately 180 years old in the 1980s,
391 we cannot rule out the stand age as another potential cause for the reduction in iWUE (Irvine et al.
392 2004; Kutsch et al. 2009; Marchand et al. 2020).

393

394 **Stem growth is decoupled from iWUE variations**

395 Our results indicate that lower radial growth rates are found with increasing peat accumulation
396 (Fig. 4). This effect was also reported in the black spruce feather moss domain of the James Bay
397 and Abitibi lowlands of eastern Canada (Harper et al. 2003; Fenton et al. 2005; Lecomte et al. 2006;
398 Simard et al. 2007). Low stem growth rates have mostly been attributed to the decrease in nutrient
399 availability induced by peat accumulation (Van Cleve and Viereck 1981; Prescott et al. 2000;
400 Simard et al. 2007). Nitrogen concentration is particularly low in peat deposits and consequently,
401 the effect of limited nitrogen availability on boreal forest growth (Macdonald and Lieffers 1990;
402 Tamm 1991; Vitousek and Howarth 1991; Maynard et al. 2014) is certainly exacerbated by
403 paludification. The thickness of the post-fire residual organic layer in which black spruce trees
404 established is thereby critical in determining tree nutrient uptake and aboveground biomass
405 production. It is well established that black spruce roots can penetrate to a depth of about 60 cm,

406 although they are generally limited to the upper 20-30 cm (Lieffers and Rothwell 1987; Viereck
407 and Johnson 1990). Trees from CAS0 and CAS50 both established in a less than 50 cm-thick
408 organic horizon, and roots could therefore easily reach the mineral soil, resulting in higher radial
409 growth rates at these sites. On the other hand, tree roots were unable reach the mineral soil layer at
410 CAS100 as black spruce trees established in a 67 cm-deep organic layer.

411

412 These findings imply that processes controlling carbon use and allocation to radial tree growth are
413 decoupled from those that control iWUE. This is in agreement with studies suggesting that iWUE
414 increases do not directly translate into enhanced radial growth (e.g., Peñuelas et al. 2011; Lévesque
415 et al. 2014; van der Sleen et al. 2015; Giguère-Croteau et al. 2019). Based on a comparison of tree
416 ring widths and eddy-covariance flux towers in boreal Canada, Pappas et al. (2020) showed that
417 aboveground biomass, and most particularly radial stem growth, represents only a minor fraction
418 (~9%) of the total gross ecosystem production (GEP). Rocha et al. (2006) also found that stem
419 growth, as estimated from tree ring widths, was not correlated to eddy-covariance-derived GEP in
420 the boreal forest of central Manitoba. These findings point into the same direction: gas exchanges
421 at the vegetation-atmosphere interface are controlled at the leaf level, but the allocation of newly
422 formed photosynthates to either above- or below-ground compartments may depend on local
423 growing conditions and site-specific growth strategies. Our study must therefore be seen as an
424 extreme case where paludification induced locally-important edaphic changes that resulted in large
425 differences in site fertility. Prioritization of belowground growth was more important in the most
426 paludified (least fertile) sites, neglecting carbon allocation to aboveground compartments. This
427 allocation strategy could reinforce tree anchoring (Nicoll et al. 2006) and enhance nutrient uptake
428 (Vicca et al. 2012; Fernández-Martínez et al. 2014), but further research is needed to shed light on
429 the processes driving allocation changes in black spruce trees.

430

431 The proportionality of the A/g_s ratio needs to be preserved between sites in order to maintain
432 comparable iWUE values across the paludification gradient (both in terms of mean and variability).
433 This implies that if A is higher in the least paludified site (e.g., CAS0) and lower in the most
434 paludified site (e.g., CAS100), then g_s will adjust in such a way to maintain nearly identical A/g_s
435 ratio, and consequently, iWUE values. Actually, we suspect that this proportional adjustment in the
436 A/g_s ratio might be an important process driving interactions between iWUE and growth rates in a
437 paludified context. As a supporting evidence for this, we found that black spruce tree ring cellulose
438 from the least paludified site (CAS0) was significantly more depleted in ^{18}O compared to that of
439 other sites (Fig. 6b). Unsurprisingly, CAS0 is also the site where radial growth rates are the highest.
440 Increased evapotranspiration rates are probably required to sustain enhanced carbon assimilation
441 and growth rates, forcing g_s to level up and proportionally adjust to increases in A (matching the
442 ratio of other sites). Consequently, higher evapotranspiration rates cause black spruce to pump more
443 ^{18}O -depleted water from soil depths (Evaristo et al. 2017), which in turns decreases average $\delta^{18}\text{O}$
444 of tree ring cellulose.

445

446 **A shift in tree response to climate in the 1980s**

447 Difference in peat thickness along the paludification gradient did not have a noticeable influence on
448 tree response to climate. Before the 1980s, tree growth from all sites showed negative correlations
449 with previous summer temperatures (Fig. 5). These climate-growth relationships have previously
450 been reported for the Canadian boreal forest (e.g., Drobyshev et al. 2010; Walker and Johnstone
451 2014; Girardin et al. 2016; Gennaretti et al. 2017). High summer temperatures in the previous
452 growing season can restrict carbon reserve accumulation, which shapes early wood development
453 the next growing season (Fritts 1976; Skomarkova et al. 2006; Campioli et al. 2011). Black spruce
454 growth also responded positively to September temperature of the current year and negatively to

455 April precipitation of the current year, which suggests that stem growth benefits from a longer
456 growing season.

457

458 After the 1980s, trees however became much less sensitive to temperature and precipitation
459 (Fig. 5). This could possibly represent a collateral effect of paludification. Interestingly, the shift
460 indicating a clear decline in black spruce sensitivity to climate is synchronous with the decline in
461 $iWUE$. The reduced sensitivity of trees to temperature since the mid-twentieth century has been
462 reported in previous tree ring studies of northern latitudinal forests, and has been referred to as the
463 “divergence problem” (e.g., Briffa et al. 2004; D’Arrigo et al. 2008; Esper and Frank 2009;
464 Schneider et al. 2014). This “divergence” phenomenon could potentially be caused by thresholded
465 responses or stresses induced by changes in growth conditions (D’Arrigo et al. 2008). The
466 important WTD deepening over the last decades (Fig. 3) might have contributed, along with stand
467 age (Szeicz and MacDonald 1994; Konter et al. 2016), to the decline in tree sensitivity to climate
468 (at the stem level) in our sites.

469

470 Overall, this study represents a first attempt to unravel the numerous and complex entanglements
471 between paludification dynamics and forest ecophysiology in the boreal forest of eastern Canada.
472 Based on our results, we conclude that taking into account factors reflecting site edaphic conditions
473 is essential to better describe and predict forest response to environmental variability, especially in
474 nutrient-limited ecosystems (Ainsworth and Rogers 2007; Kirschbaum 2011; Lévesque et al. 2016;
475 Guerrieri et al. 2019). Our findings warrant further studies of vegetation/forest dynamics models
476 and their application to forested peatlands, as those models are often biased towards converting
477 increases in $iWUE$ into increases in stem growth. For example, a successful modelling of the c_i/c_a
478 ratio based on the least-cost optimality principle (Lavergne et al. 2020) would predict comparable
479 $iWUE$ trends, regardless of the degree of paludification and with correct implications for carbon
480 and water cycle interactions at the leaf level. However, failing to account for paludification-related

481 carbon allocation strategies would result in the overestimation of aboveground biomass production
482 in sites where peat accumulation is rapid. Peatlands are one the largest natural terrestrial ecosystems
483 for carbon sequestration, and forested peatlands represent a major component of these ecosystems
484 in boreal regions (Thompson et al. 2016; Webster et al. 2018). Therefore, additional research on
485 carbon allocation strategies are of utmost importance to understanding the carbon sink capacity of
486 black-spruce-dominated boreal ecosystems.

487

488 **Conclusions**

489 In this study, we used an innovative approach to evaluate black spruce radial growth in sites
490 undergoing paludification by combining paleoecohydrological, dendrochronological, and
491 geochemical analyses. We provide the first multi-proxy tree-ring chronologies showing how radial
492 tree growth and main metabolic processes change along a paludification gradient.

493

494 Contrary to our expectations, results show that the degree of paludification does not alter black
495 spruce metabolism in boreal forested peatlands. The accumulation of thick organic layers does
496 induce stem growth decline, but this tree response to paludification is not reflected in black spruce
497 ecophysiological mechanisms. The increasing iWUE trends observed could suggest increasing
498 carbon assimilation and radial growth rates at the three sites. However, radial growth of black
499 spruce trees clearly declined with organic layer thickness, resulting in different tree aboveground
500 biomass between the study sites. This underlines that changes in iWUE are not necessarily related
501 to changes in carbon use efficiency because of site conditions (Manzoni et al. 2018). Consequently,
502 dynamic changes in edaphic conditions need to be considered in process models (Guiot et al. 2014).
503 Otherwise, based on tree ecophysiological parameters alone, comparable growth between the three
504 study sites would have been assumed. Our results thus suggest that failing to account for degree of
505 paludification in interpreting tree growth mechanisms can lead to misleading forest productivity

506 predictions in the boreal biome. This could furthermore result in a considerable overestimation of
507 carbon stocks from trees in the boreal regions where paludified forests and forested peatlands are
508 widespread.
