Abstract

Governments worldwide are implementing mass vaccination programs in an effort to end the novel coronavirus (COVID-19) pandemic. Here, we evaluated the effectiveness of the COVID-19 vaccination program and predicted the path to herd immunity in the U.S. We estimated that vaccination reduced the total number of new cases by 4.4 million (from 33.0 to 28.6 million), prevented approximately 0.12 million hospitalizations (from 0.89 to 0.78 million), and decreased the population infection rate by 1.34 percentage points (from 10.10% to 8.76%). We built a Susceptible-Infected-Recovered (SIR) model with vaccination to predict herd immunity. Our model predicts that the U.S. can achieve herd immunity by the last week of July 2021, with a cumulative vaccination coverage of 60.2%. Herd immunity could be achieved earlier with a faster vaccination pace, lower vaccine hesitancy, and higher vaccine effectiveness. These findings improve our understanding of the COVID-19 vaccination and can inform future public health policies.

INTRODUCTION

The novel coronavirus (COVID-19) pandemic has had a devastating impact on health and well-being, with more than 131 million cases and 2.8 million deaths across more than 200 countries¹ as of early April 2021. Despite various regional and national non-pharmaceutical interventions²⁻⁴ such as travel restrictions, social distancing measures, stay-at-home orders, and lockdowns, many countries continue to struggle with the growth of COVID-19 cases. It is obvious that a successful COVID-19 vaccination program is needed to end the pandemic and allow a return to normal life^{5,6}.

By the end of February 2021, two COVID-19 vaccines had been approved in the U.S.: BNT162b2 (Pfizer/BioNTech) and mRNA-1273 (Moderna)⁷. In two large randomized controlled trials (RCTs), the Pfizer vaccine exhibited an efficacy of 95% (95% confidence interval [CI], 90.3% - 97.6%)⁸ in preventing COVID-19, and the Moderna vaccine showed an efficacy of 94.1% (95% CI, 89.3%-96.8%)⁹. Both are mRNA vaccines that require two doses to complete vaccination and received emergency use authorization by the U.S. Food and Drug Administration in December 2020¹⁰. Mass vaccination campaigns with these two vaccines have since begun. By early March 2021, more than 121 million doses had been administered across the U.S., with over 43 million individuals (~13% of the population) fully vaccinated with two doses¹¹.

Although the efficacies of these two vaccines were shown to be high in RCTs, there is limited information on their potential population-level impact on the COVID-19 pandemic. One peer-reviewed study that estimated vaccine effectiveness used data from nationwide mass vaccination in Israel and reported the effectiveness of the Pfizer vaccine to be 46% (95% CI, 40%-51%) after the first dose and 92% (95% CI, 88%-95%) after the second dose for documented infection¹².

Another study that examined the effectiveness of the Pfizer vaccine among U.S. residents in skilled nursing facilities reported an estimation of 63% (95% CI, 33%-79%) after the first dose¹³.

In this study, we employed well-established reduced-form econometric techniques¹⁴, commonly used to evaluate the effects of policies or events^{15,16}, to assess the impact of vaccination during the ongoing outbreak using data from all 50 U.S. states and the District of Columbia (DC). Although the allocation of vaccines is roughly proportional to state population (Extended Data Fig. 1a), the actual proportion of the vaccinated population differs significantly across states over time (Extended Data Fig. 1b), which provides the key variation to identify the impact of vaccination. Effectively, the observations from each region in the weeks before the vaccination program served as the “control” for the observations after the vaccination program began (“treatment”), with variations in the vaccination rates leading to changes in the “treatment intensity.” By comparing the outcomes across states before and after the initiation of vaccination programs, we evaluated the impact of vaccination on the COVID-19 pandemic.

RESULTS

Study Design

We collected state-level daily infection and hospitalization data in the U.S. from 12 October 2020 to 7 March 2021. Fig. 1 shows a timeline of COVID-19 developments during this period, including important events and vaccination timeline. We aggregated the data to a weekly level in our baseline estimation given the observed weekly cycle^{17,18} (see Extended Data Table 3 for results using daily data). The dependent variables used to assess the impact of vaccination on the pandemic are the growth rates of total cases and hospitalizations. Our key independent variables are vaccination

rates, including the total number of vaccine doses administered per 100 people (at least one dose) and the total number of second doses administered per 100 people. Without any control variables, Fig. 2 shows the negative correlation between the vaccination rate and the growth rates of total cases and hospitalizations.

To make the individual states as comparable as possible, we first accounted for observable factors associated with the COVID-19 pandemic based on previous studies (see Extended Data Table 1). These time-varying control variables included non-pharmaceutical interventions⁵⁻⁷, election rallies^{19,20} and anti-racism protests²¹ that involved mass gatherings, and climate measures of snow depth and temperature²². To address the concern that changes in the number of total cases reflect the testing capacity of each state²³, we also controlled for each state's testing capacity. As the proportion of susceptible individuals declines, the infection rate may slow; therefore, we included the share of susceptible individuals in the regressions. We estimated the dependent variables of COVID-19 cases and hospitalizations with a one-week lag to account for the latency period of infection. Finally, we added state fixed effects and time fixed effects to capture spatial and temporal invariants to alleviate omitted-variable bias.

Impact of Vaccination

Our data show that the national average weekly growth rate of total cases was 7% (s.e.m. = 0.05) between 12 October 2020 and 7 March 2021. At the individual state level, the average growth rate was highest in Vermont (11%) and lowest in Hawaii (4%). The average growth rate of total hospitalizations across the 35 states that reported hospitalization data was 5% (s.e.m. = 0.04%); the highest growth rate was seen in Montana (8%) and the lowest in New Hampshire (2%).

Vaccination has significantly slowed the growth of total COVID-19 cases and hospitalizations in the U.S. Our baseline results (Fig. 3a and Extended Data Table 2) show that one additional vaccinated individual per 100 people (at least 1 dose) reduced the growth rate of total cases by 0.7% (s.e.m.= 0.2%) and the growth rate of total hospitalizations by 0.7% (s.e.m. = 0.2%). The effects of receiving full vaccination with two doses appear greater, with reductions of 1.1% (s.e.m. = 0.4%) in the growth rate of total cases and 1.1% (s.e.m. = 0.3%) in total hospitalizations. Based on these estimates (Fig. 3b), vaccination reduced the number of new cases during our study period by 4.4 million (from 33.0 to 28.6 million), which translates into a decrease of 1.34 percentage points in the population infection rate (from 10.10% to 8.76%). Vaccination further reduced the number of hospitalizations by approximately 0.12 million, from 0.89 to 0.78 million (Supplementary Methods).

If systematic correlations existed between the pre-vaccination growth rates of infection and hospitalization and the rate of vaccination, our results would have been subject to selection bias. However, this was not the case. We demonstrated that the number of vaccines allocated to each state was proportional to its population size (Extended Data Fig. 1a). More importantly, we found that the pre-vaccination average growth rates of total cases and hospitalizations were not correlated with the average vaccination rate (Extended Data Fig. 2).

Our baseline results focus on the average treatment effect of vaccination. This effect may be heterogeneous across states that have different characteristics. For example, some evidence shows that the prevalence of COVID-19 differs across age groups, with older adults bearing the highest risk^{24,25}. Because older adults were given priority during the rollout of vaccination, it is intuitive

to ask whether this strategy made a difference. We separated the states into two groups according to their proportion of older adults (at least 65 years of age). Despite the slightly larger point estimate for the states with a share of older adults above the national median, the results do not differ significantly from those for the states below the median (Extended Data Fig. 3c). In addition to age, we conducted heterogeneity tests on political affiliation, nonpharmaceutical interventions, race, income, and vaccine brand. We found no significant heterogeneous effect of vaccination on any of these characteristics (Extended Data Fig. 3), implying that COVID-19 vaccines have similar effectiveness across these characteristics.

We conducted a range of sensitivity tests. First, instead of using weekly data, we ran regressions with daily data and obtained results of similar magnitudes (Extended Data Table 3). Second, we used alternative measures to capture the development of the pandemic, including the logarithms of new cases and hospitalizations and the changes in logarithms of total cases and hospitalizations. Again, using these measures, we found that vaccination has significantly slowed the pandemic (Extended Data Fig. 4 and Extended Data Table 4). Although the vaccination rollout began on 14 December 2020, our vaccination data begin 11 January 2021; we thus used linear extrapolation to impute the missing data. Our results with the inclusion of imputed data are very similar to the baseline results (Extended Data Fig. 5). Finally, we selected approximately the same number of weeks for the pre-treatment and post-treatment periods to balance the sample in our baseline results. To check the sensitivity of our results to the sample period, we ran our regressions with varying time windows, and our results remain remarkably stable. We obtained approximately the same coefficients for sample periods from 18 to 45 weeks (Extended Data Fig. 6).

Herd Immunity

To predict how the pandemic will develop with vaccines, and especially when herd immunity might be achieved, we built a Susceptible–Infected–Recovered (SIR) model with vaccination and calibrated it to our data. Our model predictions of the infection rate during the study period showed 99.69% correlation with the empirical data at the national level (Extended Data Fig. 7). Herd immunity is achieved in the model when the real-time basic reproduction number is less than one (Supplementary Methods).

According to our model predictions, at the national average vaccination pace of 2.08 doses per 100 people per week between January and early March of 2021, the U.S. will achieve herd immunity around the last week of July 2021, with a cumulative vaccination coverage rate of 60.2% and a cumulative infection rate of 13.3%. To understand how the speed of vaccination rollout would affect the time needed to reach herd immunity, we simulated herd immunity dates by varying vaccination pace (Fig. 4). We observed a general trend that a faster vaccination pace would allow the U.S. to achieve herd immunity sooner, but with a greater number of total vaccine doses administered and a lower cumulative infection rate. This result can be explained as more individuals gaining immunity from vaccines than from infections if the vaccination pace increases. If the vaccination pace increases to 4 doses per 100 people per week, herd immunity could be reached in early May 2021, but if it decreases to 1 dose, herd immunity would not be achieved until mid-October 2021.

Our predictions of herd immunity assume a continuation of vaccine uptake. In reality, however, a few potential factors could affect uptake. A certain proportion of the population might not receive

the vaccination due to vaccine hesitancy. Studies have shown that vaccine hesitancy is a common phenomenon in the U.S.^{26,27}, where some individuals are reluctant to receive vaccines due to the perceived risks versus benefits, certain religious beliefs, and a lack of trust in government²⁷. Another issue is the effectiveness of vaccines against new coronavirus variants²⁸. Only limited evidence is available regarding the efficacy or effectiveness of the Pfizer and Moderna vaccines against these new variants²⁸.

To examine how vaccine hesitancy and changes in vaccine effectiveness could affect our predictions for herd immunity, we incorporated in our model a range of potential vaccine hesitancy and vaccine effectiveness estimates. We assumed that if $x\%$ of the population is hesitant, then cumulative vaccination coverage in each state will stop when $(1 - x\%)$ of the population is vaccinated. Table 1 shows that a higher percentage of vaccine-hesitant individuals will lead to lower vaccination coverage with more individuals infected with COVID-19 at herd immunity. In particular, if vaccine hesitancy reaches 50%, herd immunity will be delayed until the end of August, with a cumulative infection rate of 14.9%; that is, 14.9% of the total population will have been infected with COVID-19 by then. This level of vaccine hesitancy is plausible, given that approximately 40% of U.S. Marines have declined vaccination²⁹. In our baseline model, the effectiveness of the first dose of the vaccine was approximately 73% (Supplementary Methods). If the vaccine effectiveness increases, fewer individuals will require vaccination to reach herd immunity, resulting in fewer cumulative cases. However, if the vaccine effectiveness decreases to 60%, herd immunity will not be reached until the week of August 16, 2021, with a cumulative vaccine coverage of 67.6% and a cumulative infection rate of 14.7%.

A few unanswered questions could still affect herd immunity. One key issue is how long the vaccine immunity will last. Definitive evidence regarding the duration of immunity protection is lacking³⁰. Another issue is moral hazard, that is, whether vaccinated individuals will change their behaviors and undertake more social interaction³¹. This change could result in higher risks of infection and a delay in reaching herd immunity.

DISCUSSION

Our study has a few limitations. We covered only the early periods of vaccination rollout, when the demand for vaccines was greater than the supply. As more individuals become vaccinated, the vaccination pace will likely slow due to the decrease in demand. In addition, our model predictions assume a continuation of the non-pharmaceutical interventions in place in early March. Relaxation of these policies would likely increase the time needed to reach herd immunity. Our SIR model assumes that only susceptible individuals undergo vaccination. However, in real life, many individuals who recovered from COVID later received vaccines. As a result, our model predictions are optimistic, and herd immunity will be achieved later based on this empirical fact. In addition, our study assessed the effects of vaccination in the U.S. using mRNA vaccines. More studies are needed to study vaccination in other countries using different types of vaccines.

Our study provides strong evidence that vaccination has significantly decreased COVID-19 cases and hospitalizations in the U.S. At the average pace of vaccination between January and early March, our model predicts that herd immunity will be achieved around the last week of July 2021, with a cumulative vaccine coverage of 60.2% and a total infection rate of 13.3%. These findings provide grounds for optimism that the pandemic will end during 2021 in the U.S. However, a few

factors, such as moral hazard, vaccine hesitancy, and variants of the SARS-CoV-2 virus, could lead to changes and cast doubt as to whether herd immunity can be achieved after all.

METHODS

Data Collection and Processing

A summary is provided of the data used in our analysis. Our supplementary notes give further details, including a summary statistics table for all variables.

Epidemiological and Vaccination Data We collected our state-level epidemiological data (total COVID-19 cases, hospitalization, and tests) from the COVID Tracking Project³², a commonly cited source³³⁻³⁵. The vaccination data across states were obtained from the U.S. Centers for Disease Control and Prevention’s (CDC) COVID data tracker³⁶, where “people vaccinated” reflects the total number of people who have received at least one vaccine dose, and “people fully vaccinated” reflects the number who have received both doses prescribed by the vaccination protocol. We downloaded the CDC vaccination data from an open-source GitHub project by Our World in Data³⁷. Both the BNT162b2 (Pfizer/BioNTech) vaccine and the mRNA-1273 (Moderna) vaccine require two doses⁹. In addition, the CDC shares data on COVID-19 vaccine distribution allocations by state for both the Pfizer³⁸ and Moderna³⁹ vaccines, as provided by the Office of the Assistant Secretary for Public Affairs under the U.S. Department of Health & Human Services.

Nonpharmaceutical Interventions In addition to epidemiological data, we obtained information on nonpharmaceutical intervention policies. We adopted the policy stringency index constructed by the Oxford COVID-19 Government Response Tracker⁴⁰, which systematically collects information on various policy responses implemented by various governments in response to the pandemic. We focused on the policy category of “containment and closure,” which covers eight policies: school closings, workplace closings, cancelation of public events, restrictions on

gathering sizes, cessation of public transportation, stay-at-home requirements, restrictions on internal movement, and restrictions on international travel. This stringency index is a weighted score across these eight containment and closure policies and is scaled between 0 and 100. A detailed explanation of these measures was given by Hale et al. (2021)⁴¹. We determined the stringency index for each state on a weekly basis by averaging the daily data.

Meteorological Data Another set of important independent variables included in this study regarded the local climate. We obtained station-level hourly weather data provided by the National Centers for Environmental Information⁴². These station-level weather data were then matched with the station location and corresponding state provided by the Global Historical Climatology Network Daily⁴³. We calculated the average values from these weather reports for each week across all stations within each state. Given the lack of humidity data, temperature and snow depth were used as our climate measures.

Election Rallies and Black Lives Matter (BLM) Demonstrations Several large-scale mass gatherings for political campaigns and protests also occurred during our study period. We constructed binary measures for election rallies⁴⁴. For states with a rally during week t , this binary measure takes the value of 1 for week t and for the week after ($t+1$). Our BLM data from Elephrame offered detailed information (date, location, etc.) about each demonstration from news reports⁴⁵, which were extracted using a Web scraper. We then calculated the total number of demonstrations that occurred across all cities within each state for each week.

Sociodemographic Data We also collected the sociodemographic characteristics of each state's population using 2019 estimates from the U.S. Census Bureau^{46,47}. Specifically, we downloaded data on age, race, and income. We constructed each of our sociodemographic variables to be binary, above or below the national median. We derived the proportion of individuals 65 years of age and older in the population, the proportion of the white population, and the income for each state to calculate a national median. Finally, our data for the 2020 Electoral College results were obtained from the National Archives⁴⁸. We classified the states into those won by Joe Biden and those by won by Donald Trump.

Econometric Analysis

Reduced-Form Analysis The following reduced-form empirical model was used to estimate the impact of vaccination on the pandemic:

$$y_{i,t} = a_0 + a_1 Vaccination_{i,t-1} + a_2 \frac{S_{i,t-1}}{L_i} + a_3 \frac{Test_{i,t-1}}{L_i} + a_4 X_{i,t-1} + b_i + c_t + \varepsilon_{i,t}. \quad (1)$$

Here, y_{it} is the dependent variable that measures the growth of either total cases or total hospitalizations in state i at period t . Our baseline measure is the growth rate, which is defined as $\frac{C_{i,t} - C_{i,t-1}}{C_{i,t-1}}$ for total cases and $\frac{H_{i,t} - H_{i,t-1}}{H_{i,t-1}}$ for total hospitalizations, where $C_{i,t}$ and $H_{i,t}$ are the cumulative numbers of cases and hospitalizations. Alternative outcome measures were also used in the sensitivity analysis (Extended Data Fig. 4).

Our key independent variable, $Vaccination_{i,t-1}$, is the rate of vaccination of state i in period $t-1$, and a_1 is the coefficient of interest. We used two measures of vaccination rate: the number of vaccinated people (i.e., those who had received at least one dose of vaccine) per hundred and the number of fully vaccinated people (i.e., those who had received two doses of vaccine) per hundred.

As the proportion of susceptible individuals in the total population decreases over time, the growth rate of infection may also decline. To deal with this intrinsic dynamic, $S_{i,t-1}/L_i$ was included in the regression model to control for the stock of susceptible individuals $S_{i,t-1}$ in the total population L_i . We measured $S_{i,t-1}$ as the difference between the population size and the total number of infections. To adjust for differences in testing intensity across states, we added $Test_{i,t-1}/L_i$ to control for the number of tests relative to the total population.

Our control variables, $X_{i,t}$, contain a dummy variable $rally_{i,t}$, which equals 1 when an election rally occurred in state i at period t . We also added a variable $protest_{i,t}$, which is the number of protests held across all cities in state i at period t . To capture the influence of climate on the pandemic, we included measures of state-level meteorological conditions, including average temperature, temperature deviation from the state mean, and the logarithm of the average snow depth. Note that we included state fixed effects (b_i) to capture state-specific unobserved factors, which are time-invariant, such as location, geography, and culture. We also included week fixed effects (c_t) to capture unobserved shocks, which are common across states, such as macroeconomic conditions. Finally, $\varepsilon_{i,t}$ is a random error term of the model, which has a mean of zero.

We estimated equation (1) using the method of Ordinary Least Square with weekly data for 50 states and DC in the baseline. Robust standard errors for the estimated coefficients with two-way clustering were calculated at the state and week levels⁴⁹. Therefore, we allowed for within-state autocorrelation in the error term to capture the persistence of the pandemic within each state. We

also allowed for spatial autocorrelation in the error term to capture common pandemic shocks or systematic misreporting across states.

Model Summary We modified a conventional SIR model with the addition of vaccination to simulate the development of the COVID-19 pandemic in the U.S. with vaccine rollout, including both state-level and national-level estimates. The theoretical SIR model with vaccination is as follows:

$$\begin{aligned}\frac{dS_{i,t}}{dt} &= -\beta_{i,t}S_{i,t}I_{i,t} - e\delta_{i,t}, \\ \frac{dI_{i,t}}{dt} &= (\beta_{i,t}S_{i,t} - \gamma_i)I_{i,t}, \\ \frac{dR_{i,t}}{dt} &= \gamma_i I_{i,t} + e\delta_{i,t}.\end{aligned}\tag{2}$$

Here, $S_{i,t}$ is the state-specific (i) and time-varying (t) proportion of susceptible individuals in the population, $I_{i,t}$ is the proportion of infected individuals, and $R_{i,t}$ the proportion of recovered (plus dead) individuals. $\beta_{i,t}$ is the infection rate, which determines the spread of the pandemic. γ_i includes both recovered individuals and deaths and is referred to as the removal rate⁵. Here γ_i varies only by state and not over time. $\delta_{i,t}$ is the proportion of vaccinated individuals, and e is the population-level vaccine effectiveness, which remains the same across states and time.

We fit the SIR model above with state-level COVID-19 epidemiology data, from which we observed data on the cumulative number of cases, deaths, and vaccination doses administered. Only 29 of the 51 states (counting DC as a “state” for this purpose) reported valid recovery data. We imputed the missing data for the other 22 states with the median recovery and mortality rates from the known 29 states (see Supplementary Methods for details). We first estimated the infection rate ($\beta_{i,t}$) and vaccination coverage ($\delta_{i,t}$). To capture the impact of nonpharmaceutical

interventions on the spread of COVID-19⁴⁻⁶, we used the following equation to estimate the infection rate with state fixed effect (ρ_i) and time fixed effect (ρ_t):

$$\beta_{i,t} = \theta_0 + \theta_1 \cdot policy_{i,t} + \rho_i + \rho_t + \varepsilon_{i,t}^\beta. \quad (3)$$

Similarly, we estimated vaccination coverage using the following equations, controlling for state and time fixed effects.

$$\delta_{i,t} = \eta_0 + \iota_i + \iota_t + \varepsilon_{i,t}^\delta. \quad (4)$$

We adopted two vaccination measures in our data: the total number of people who had received at least one vaccine dose and the total number of fully vaccinated people. No time trends were observed in the total doses administered for at least one dose of vaccine, but an apparent time trend was seen in the doses administered for the second dose. We therefore added a time trend in the estimation equation above when we conducted the sensitivity check using the total number of fully vaccinated people as our measure of vaccination. We used equations (3) and (4) to estimate the infection rate and vaccination coverage, combined with the initial epidemiological data of SIR in week 1 (12 October 2020), and our model estimates of the infection rate for the following 20 weeks are highly correlated with the empirical data. For each individual state, our model estimates reached a median correlation of 99.04% (range, 86.37% to 99.95%) (Extended Data Fig. 7).

We assessed herd immunity based on our model estimates of the real-time basic reproduction number for each state, $R'_{i,t} = \frac{\beta_{i,t} S_{i,t}}{\gamma_i}$; that is, the number of cases directly caused by an infected individual throughout his or her infectious period. The model achieves herd immunity when $R'_{i,t}$ falls below 1 in 49 states (except for Maryland and Kentucky; see Supplementary Methods for details).

For each given vaccination pace, we ran the simulation forward and projected the future dynamic of the pandemic across the U.S., assuming that no changes are made in nonpharmaceutical interventions. We then computed the time required for every state to achieve herd immunity and calculated the share of the U.S. population vaccinated when herd immunity is achieved. In addition, we conducted a sensitivity analysis regarding herd immunity with variations in vaccine effectiveness and with the addition of vaccine hesitancy. We incorporated vaccine hesitancy into our model by assuming that if $x\%$ of the population is hesitant, the cumulative vaccination coverage in each state will stop when $(1 - x\%)$ of the population is vaccinated.
