Abstract

Background In order to complete the physiological function of postovulatory repair during repeated ovulation, the ovarian surface epithelium (OSE) not only has to undergo epithelial-mesenchymal transition (EMT), but also possess the properties of somatic stem-like cells. However, there is no evidence to indicate that both EMT alteration and stemness acquisition are linked to epithelial ovarian carcinomas. **Methods** In this study, we established a cell model of spontaneous oncogenic transformation of mouse OSE (MOSE). The cell proliferation was assessed using clonogenic survival and soft agar. The self-renewal of cancer stem-like cells (CSCs) was determined by spheroid culture. CD44 + /CD117 + cells were analyzed using flow cytometer. The PCR array was used to determine the EMT-related mRNA level. Expression of pan-keratin, vimentin, E-cadherin, Snail1 and Slug were detected using western-blotting and immunofluorescences, respectively. The tumorigenesis were monitored by limiting dilution assay in vitro and in vivo . **Results** Based on morphological change, chromosomal number and proliferating ability, we defined three sequential stages of transformed cells as early, intermediate and late MOSE cells, respectively. We found that MOSE cells had dual characteristics of not only epithelial but mesenchymal nature as well. Over time, MOSE cells spontaneously developed characteristics of malignant cells and generated tumor nodules expressing both Pan-keratin and Vimentin. Furthermore, we found that the neoplastic transformation of MOSE was accompanied by continuous EMT-inducing signals including Snail1 and Slug. Concurrently, the increase of CD44 + /CD117 + cells and their self-renewal ability were associated with the progression of spontaneous neoplastic transformation of MOSE cells in vitro. **Conclusion** These results indicated that both EMT alteration and stemness acquisition were closely correlated with the spontaneous malignant progression of MOSE cells. Our findings provide new insights into the future to combat epithelial ovarian carcinomas.

Background

Ovarian cancer is a deadly gynecologic malignancy with a five-year survival rate of less than 30% [1]. The poor prognosis is largely due to difficulties in its early diagnosis and the high rate of relapse as a result of chemoresistance. Epithelial ovarian carcinomas (EOC) account for 90% of all ovarian malignancies [2] and comprise multiple subtypes [3]. The early events of EOC development are poorly understood and the exact initiating cell population remains to be defined.

Ovarian surface epithelium (OSE), a single layer of squamous or cuboidal cells, plays physiological roles in both follicular rupture and subsequent ovarian remodeling by altering the motility and proliferation response necessary for extracellular matrix remodeling. OSE can undergo proliferative repair, and its normal regulation may contribute to the pathogenesis of EOC [4]. In addition, OSE has been postulated as the source of EOC base on pathological observations and experimental approaches [5-8].

The capacity of OSE that undergoes epithelial-mesenchymal transition (EMT) in response to postovulatory stimuli has been proposed to confer advantage to the postovulatory repair of the epithelia cells [9]. Hence, EMT is a part of normal OSE physiology and failure in this process may be the reasons of

ovarian cancer initiation and metastasis. Additionally, the cyclic pattern of repeated disruption and repair with complex remodeling associated with ovulation leads one to intuit the existence of a population of somatic stem cells that would be responsible for these processes. OSE with some stem-cell properties have been identified previously based on their slow proliferation [10]. In addition, OSE at the junction area contains cancer-prone stem cell niche [11]. Moreover, accumulating evidence supports that EMT and cancer stem cells (CSCs) play critical roles in the development of chemoresistance, tumor relapse and metastasis in ovarian cancer patients [12-14].

In order to complete the physiological function of postovulatory repair during repeated ovulation, OSE not only has to undergo EMT, but also possess the properties of somatic stem-like cells. The current literatures on the existence of somatic stem cells and EMT-associated events in normal OSE have discussed its implication for normal ovarian function as well as neoplastic phenotypes [9, 15-18]. Distinctly, OSE possesses extraordinary cellular proliferative capacity without reaching crisis phase [19], while other adult epithelial cells undergo a restricted number of population doublings before senescence *in vitro*. Several experimental models have recently been developed to study the transformation of OSE, including genetically modified mouse models and manipulation of cultured human OSE cells [20-28]. In addition, the transcriptional profile of ovarian carcinomas was investigated [9, 16, 18]. There is, however, no evidence indicating that EMT alteration and stemness acquisition are involved in the spontaneous transformation of OSE cells.

The isolation and culture of human and mouse ovarian surface epithelium have been described [24, 27, 28]. Therefore, taking advantage of the spontaneous transforming of OSE cells, we established a step-wise neoplastic transformation model of these cells from a premalignant phenotype to the malignant one. We also demonstrated that the alteration of EMT and acquisition of stem-like properties were associated with the neoplastic process of mouse OSE cells.

Methods

Cell isolation and culture

Mouse ovarian surface epithelial (MOSE) cells were isolated as described by Roby and Paul et al [1-3], and modified by us. Briefly, ovaries from female C57BL/6 mice (Experimental Animal Center for Soochow University,) were resected and, were incubated for 20 min in Dulbecco's Modified Eagle's Medium/Nutrient Mixture F-12 (DMEM/F12, Invitrogen, Carlsbad, CA) supplemented with 0.25% trypsin (Invitrogen, Carlsbad, CA). Single cells and clumps of MOSE were collected, resuspended in MOSE cell growth medium, and seeded onto 35 mm dishes in a humidified atmosphere of 5% CO₂ at 37 °C. The MOSE cell growth medium consisted of DMEM/F12 medium supplemented with 5% fetal bovine serum (FBS), 10 ng/ml mouse epidermal growth factor (mEGF), 100 U/mL penicillin and 100 µg/mL streptomycin (Beyotime Biotechnology, shanghai, China), 1% insulin-transferrin-selenium (Invitrogen, Carlsbad, CA). During early passages of cells (pass 1 through 20), medium was changed with the mixed medium containing a 1:1 of the fresh growth medium and culture supernatant. Intermediated (pass 21-90) and

late passage (greater than 90) cells were routinely passaged. This animal experiment was performed according to the protocols of the Institutional Animal Care and Use Committee of the Soochow University (IACUCSU).

Cell proliferation assay

Cell proliferation was detected by Cell Count Kit-8 (CCK-8; Dojindo Laboratories, Kumamoto, Japan). In brief, cells were plated in 96-well plates at a density of 1000 cells per well and cultured in growth medium. At specific points in time after plating (0, 7, 24, 48, 72, 96, and 120h), the cell counts were determined according to the manufacturer's instructions.

For clonogenic survival assay, five hundred cells were seeded into dishes 35 mm in diameter. After two weeks, the colonies formed were fixed with formaldehyde, stained with Giemsa, and counted using a colony counter soft at GBOX XR-5 (Gene Company Limited, HongKong, China). The plating efficiencies (PE) were determined using the following formula: PE (%) = number of colonies formed / 500 plated cells × 100%. All data points in figures represent three independent experiments.

Soft agar colony formation assay

Two thousand cells were suspended in 1 mL of 0.35% agarose in the growth medium, plated into 35 mm dishes with a bottom layer of 0.7% agarose. Cells were fed every 3 days with 1 ml growth medium. Colonies (>15mm) were counted two or three weeks after seeding. Data are presented as CFU (percent colony forming units in soft agar assay) = mean of the number of colonies per dish/number of cells seeded per dish × 100%. Data points in figures represent three independent experiments.

***In vivo* tumorigenicity assays**

Ten female BALB/c nude mice (SPF, 4-6 weeks, 18-20g) were bought from Experimental Animal Center for Soochow University, and they were housed under temperature-controlled conditions, underwent a reverse dark-light cycle, and provided with standard mouse pellets and tap-water *ad libitum*. The mice were randomly divided into three groups (n=3) including M-E group, M-I group and M-L group for injection MOSE cells. After animals were lightly anesthetized with isoflurane, 5×10^6 of cells were injected subcutaneously into the left and right flanks of each animal. Animals were palpated weekly for tumor formation. Tumor size was measured once per week and tumor volume was calculated using the formula, tumor volume = $0.5 \times \text{length} \times \text{width}^2$. Animals were killed as soon as tumor nodules reached a size of 1.2–1.5 cm. The euthanasia/sacrifice of the mice was used by excessive 3% pentobarbital sodium (0.1 ml/10 g), following cervical dislocation to ensure the death of mice. This animal experiment was performed according to the protocols of the IACUCSU.

PCR Array

The total RNA was isolated from 10^6 cells using TRIZOL (Life Technologies). cDNA was synthesized from 500 ng of the total RNA using the RT² first strand kit (SABiosciences, Frederick, MD). After all the control

tests, the samples were analyzed using the mouse EMT RT² profiler PCR array (PAMM-090Z, SABiosciences, Frederick, MD) that profiles the expression of 84 key genes. Altogether 84 different genes were simultaneously amplified in each sample. Five house-keeping genes (B2M, HPRT1, RPL13A, GAPDH, and ACTB), genomic DNA contamination control, reverse transcription control and positive PCR control were included in each PCR array. Briefly, the reaction mix was prepared from 2× SABiosciences RT² qPCR master mix and 102 ml of sample cDNA. Ten ml of this mixture was added into each well of the PCR array. PCR arrays were performed in 384-well plates on a 7500 real time PCR system (Applied Biosystem, Foster City, CA).

Spheroid culture

Sphere formation assay was performed using serum-free DMEM/F12 Medium, including 20 ng/mL mEGF, 20 ng/mL basic fibroblast growth factor, 100 U/mL penicillin and 100 µg/mL streptomycin, 2 mg/ml insulin, 4 mg/mL heparin sodium, and 6 mg/mL glucose. Late MOSE cells were plated at a density of 1000 cells in 35 mm dish and cultured for 10 days. Round cell clusters larger than 100 µm were judged as spheres. Data was presented as sphere formation efficiency (%) = (number of spherical formation/plated cells × 100%). Data points in figures represent three independent experiments.

Limiting dilution assay

Limiting dilution assay was performed to measure the number of cells required to generate at least 1 tumor sphere/well as previously described [29]. Briefly, serial two fold dilutions of M-I (from 0 to 5000 cells) and M-L cells (from 0 to 500 cells) were sorted into ultra-low 96-well plates with 6 wells per dilution, respectively. Cultures were fed 50 µl of CSCs medium every 2 days until day 10. Fraction of wells without spheres (y-axis) was plotted against the number of cells plated per well (x-axis). Regression lines were plotted and x-intercept values calculated, which represent the number of cells required to form at least 1 tumor sphere in every well.

Western-blotting

Proteins were extracted with lysis buffer (Beyotime Biotechnology, Shanghai, China). The protein concentration of lysate was quantified using a bicinchoninic acid protein assay kit (Beyotime Biotechnology). Equal amounts of total proteins (30 µg) were electrophoretically transferred onto a polyvinylidene fluoride membrane (Millipore, Boston, MA). After being blocked with 5% skimmed milk, the membranes were incubated with primary antibodies of pan-keratin, vimentin, E-cadherin, b-catenin, Slug, Snail, Nanog, and β-actin (Cell Signaling Technology, Danvers, MA) at a 1:1000 dilution. Secondary antibodies were purchased from Amersham Biosciences (Piscataway, NJ) and the immune complexes were detected using an enhanced chemiluminescence (Millipore, Boston, MA) method according to the manufacturer's instructions.

Immunofluorescences

Cells were plated into micro-slides, and then fixed in 4% paraformaldehyde. Cells were permeabilized with 0.5% Triton followed by blocking with 5% BSA for at least 30 minutes at room temperature (RT). Incubations with primary antibodies were carried out for overnight at 4°C. Appropriate secondary antibodies conjugated to either AlexaFluor 488, AlexaFluor 543, or AlexaFluor 635 were carried out for 30 min at RT. Nuclear was counterstained with 4',6-diamidino-2-phenylindole (DAPI). Image was observed using SP5 confocal laser scan microscope (Leica, Wetzlar, Germany).

Flow cytometry assay

For stem cell marker analysis, 10^6 cells were resuspended in PBS, incubated with fluorescence-conjugated monoclonal antibodies against CD44-FITC and CD117-PE (BD Pharmingen) at 4°C for 10 min, and washed by PBS for 3 times. The samples were analyzed by FC500 flow cytometer (Beckman Coulter, Fullerton, CA).

Histology and immunohistochemistry

Resected ovaries and tumors were collected from mice, fixed in 4% paraformaldehyde. Routine paraffin embedding of tissues and hematoxylin and eosin staining of tissue sections were performed by histopathological laboratories of Soochow University (Suzhou, China). For immunohistochemistry, tissues were cut into 5 μm sections. Slides were deparaffinized and rehydrated in an ethanol series. The sections were treated with 3% H_2O_2 /MET for 20 min and boiled with citrate buffer (0.01 M, pH 6.00), then incubated overnight with indicated primary antibodies at 4°C. After that, followed with PBS washed for 3 times, the slides were then incubated with secondary antibodies with HRP. The slides were incubated with DAB solution, and then counterstained with hematoxylin according to standard protocols.

Statistical analysis

Data were presented as mean \pm standard deviation (SD), and were analyzed with one way analysis of variance (ANOVA) and Student's t-test. $P < 0.05$ were considered statistically significant.

Results

The spontaneous neoplastic transformation of MOSE cells *in vitro*.

It is well known that primary epithelial cells stop replication after ~ 10 passages *in vitro*. Owing to the specific physiological role of ovarian remodeling during ovulation, it is possible that OSE continues to proliferate when subcultured *in vitro*. We wondered whether establishing a cell model of spontaneous epithelial ovarian cancer represented distinct transitional states of neoplastic progression. We first isolated primary MOSE cells from mouse ovary and cultured them *in vitro*. The MOSE showed typical cobblestone-like phenotype and maintained contact inhibition of growth. The culture media used in the first 20 passages consisted of a 1:1 mixture of fresh and conditioned medium of existing cultures, which was different from previous report [24, 28] but proved to be crucial to maintain the cultures. The

cultivation of these early, MOSE cells gradually entered the intermediate stage when cells displayed more spindle-shaped morphology and loss of cell-cell contact. MOSE cells finally converted into spindle-like mesenchymal morphology as evidenced by their multi-layered growths (Fig. 1A). Interestingly, MOSE cells were positive for both Pan-keratin and Vimentin during the long-term *in vitro* culture (Fig. 1B, C and D), suggesting that they had a dual characteristics of not only epithelial but mesenchymal nature as well.

To further elucidate these transitional stages, we determined the capacity of anchorage-independent growth, an *in vitro* hallmark of neoplastic transformation of cells. Both early (<20 passages) and intermediate (21-80 passages) MOSE cells were unable to form colonies in soft agar. Notably, late-passage (>81) MOSE cells were capable of forming >30 mm colonies but at diminished efficiency compared with human ovarian cancer SKOV-3 cells (Fig. 2A). Compared with MOSE cells at earlier stages, late-passage MOSE cells exhibited dramatically increased plating efficiency and growth rate, another proliferative parameter that is often associated with neoplastic change (Fig. 2B and C). The average chromosomal number observed in early passages MOSE cells was 49, and 36% of cells at this stage were hyperdiploid. But as the cells progressed, there was a trend toward increased numeric abnormalities. In the late-passage cells, the average chromosome number was 64, with 43% were near-tetraploid and hypertetraploid (Fig. 2D). Therefore, based on morphological change, chromosomal number and proliferating ability, we defined three sequential stages of transformed MOSE cells as M-E (≤ 20 passages), M-I (21-80 passages) and M-L (≥ 81 passages) cells, respectively.

Tumorigenicity of MOSE cells *in vivo*

To assess oncogenic transformation of MOSE cells *in vivo*, we subcutaneously injected them into athymic nude mice. As expected, M-L cells formed tumors in three of three animals within four weeks post-injection. In contrast, M-E cells did not form any tumor by 12 weeks post-injection (Fig. 3A). Although M-I cells formed smaller nodules with average volume of 17 mm³, HE staining showed only infiltrated lymphocytes (Fig. 3B and C). However, M-L cells developed relative fast growing tumors with an average volume of 1475.86 mm², and showed malignant cells with a large nuclear to cytoplasmic ratio and neovascularization (Fig. 3). These tumor nodules showed high level of both Pan-keratin and Vimentin, indicating that they were similar in phenotype to that of epithelial ovarian cancer [9, 19, 30] (Fig. 3D). These results showed that MOSE cells, over time, spontaneously develop characteristics of malignant cells and generate tumors consistent with epithelial ovarian cancer. Thus, progression of MOSE cells from a benign to a malignant phenotype *in vitro* may provide a model to dissect the progression of ovarian cancer.

EMT alteration was accompanied with spontaneous oncogenic-transformation of MOSE cells

EMT is believed to be an essential part of post-ovulatory remodeling process [9, 31]. To determine whether the spontaneously transformed MOSE cells undergo EMT, we compared EMT-related gene expression profiling by using high-throughput EMT profiler™ PCR array. Figure 4 shows that the expression of EMT-related genes, specifically Spp1, Wnt11, Cav2, Cald1, MSN, Jag1 and Vps13a, are

markedly increased both in M-I and M-L cells. On the other hand, the level of mRNA down-regulated during EMT included Wnt5b, Ptp4a1, Mmp2, Mmp3, Col3a1, and Esr1. These genes were strongly reduced in malignant progression of MOSE cells (Fig. 4A, 4B and 4C). Furthermore, the mRNA levels of EMT-induced transcription factors (Snail, Slug, Tcf4 and Tgfb2) were significantly up-regulated, and those of epithelial markers (Krt19 and Krt7) were down-regulated in M-L cells (Fig. 4A). Indeed, the results of immunofluorescence studies also showed an increased expression of Snail and Slug in M-L cells, compared with M-E cells, as demonstrated by western-blotting analysis (Fig. 4D). Interestingly, level of E-cadherin and b-catenin in M-I cells increased dramatically (Fig. 4E). Collectively, as illustrated by the mesenchymal morphology of M-L cells shown in Figure 1A, these results indicated that the neoplastic transformation of MOSE was accompanied by continuous EMT-inducing signals including notable increase of Snail and Slug.

Stem-cell-like properties were correlated with neoplastic transformation of MOSE cells

There is recent evidence that OSE at the junction area contains a cancer-prone stem cell niche [10, 11, 31]. We wondered whether the neoplastic transformation of normal surface epithelial cells correlates with acquisition of stemness. So, the stem cell-like properties of MOSE cells were monitored during their long-term culture *in vitro*. The percentages of CD44⁺ and CD117⁺, markers for ovarian cancer stem cells, were found to be up-regulated post neoplastic transformation of MOSE cells (Fig. 5A). Consistently, mRNA of stem-related genes, such as Nanog and Sox2, gradually increased and KLF4 decreased during malignant progression of MOSE cells (Fig. 5B). Interestingly, the M-L cells displayed obviously self-renewal properties, which formed larger and more spheres from a single cell suspension under serum-free medium. The sphere forming efficiency (SFE) was markedly higher in M-L cells, compared with that in M-E and M-I cells (Fig. 5C). These findings suggested that stem-like cells in ovarian surface epithelium might be involved in the progression of spontaneous neoplastic transformation of MOSE cells *in vitro*.

A single tumor sphere resulting from the proliferation of a single cancer stem cell coupled with limiting dilution analysis allows for the determination of the minimal frequency of repopulating tumor sphere cells within the cell population. Figure 5D revealed that at least 1072 M-I cells were required to generate one tumor sphere, whereas 431 M-L cells were required. M-L cells formed tumors in nude mice within 4 weeks after 10⁶ cells were subcutaneously injected. However, sphere forming cells produced tumors at 5 of 5 sites with 10⁵ cells at each site within two weeks. Furthermore, expression of CD44 based on immunofluorescence staining was higher in tumor tissue injected by sphere forming cells than that of M-L cells (Fig. 5E). Taken together, these results further suggest that stem-like acquisition of MOSE cells are closely correlated with the development of ovarian cancer.

Discussion

In this study, we report, for the first time, that both EMT alteration and stemness acquisition are closely correlated with the spontaneous neoplastic transformation of MOSE cells during long-term culture *in vitro*. Primary MOSE cells maintained proliferation and underwent spontaneous neoplastic

transformation when subcultured for more than 80 passages *in vitro*, an observation consistent with several earlier reports [24, 26-28].

It is widely accepted that transformation process often involves alteration of oncogenes and/or tumor suppressor gene. Several experimental models have been developed to study the transformation of genetically modified OSE, including K-ras [22], KLF8 [20], Akt1 [32], p53 and Rb1 [33]. Although these genetic models provide important insights into ovarian tumor biology, they are not representative of the heterogeneous and spontaneous nature of EOC. It is unclear whether alteration of EMT, physiologic function of normal ovarian surface epithelial, may be conducive to OSE transformation.

The single-layered epithelial cell structure of human OSE belies its complex biology. Due to its active role in both follicular rupture and subsequent ovarian remodeling, OSE possesses extraordinary cellular proliferative capacity *in vitro*, which often promotes the transformation of these epithelial cells [9, 19]. The capacity of OSE to undergo EMT in response to postovulatory stimuli has been proposed to confer advantage to the postovulatory repair of the OSE. Hence, EMT is a part of normal OSE physiology and failure to undergo such process may be one of the reasons of the initiation and metastasis of ovarian cancer. The fact that OSE can transit back and forth between epithelial and mesenchymal phenotypes is believed to be part of the normal process of post-ovulatory ovarian remodeling [9, 31]. We also found that primary MOSE cells showed a dual nature of not only as epithelial but also as mesenchymal cells, and demonstrated that spontaneously malignant transformation progressed with a concomitant increase in EMT-transcription factor Snail and Slug. Additionally, the normal OSE is not only a somatic stem cell source given its role in repeated ovulation, but also a potential progenitor of EOC. Cancer-prone stem cell niche was identified on the OSE [11]. Consequently, whether stem-cell properties and EMT alteration are involved in malignant transformation of OSE remains incompletely understood. After the models established by Robe and Pauc et al. [24, 28], we have again identified that mouse OSE cells can spontaneously undergo neoplastic transformation during *in vitro* culturing. In our model, three transitional stages including early, immediately and late, were distinguished by morphologic phenotypes, the alteration of both EMT and stemness, proliferation *in vitro* and *in vivo*.

M-E cells represent the earliest transitional state of our model, characterized by typical cobblestone-epithelial appearance, a slow growth rate, and inability to anchorage-independent growth. They favor strong cell-substratum as well as cell-cell contact. Interestingly, in this stage, the stem and/or progenitor cell markers, such as CD44 and CD117 were often detected, even though in low proportion. The existence of somatic stem cells is likely to reside in distinct tissue compartments of the female reproductive system, because of the control for menstrual cycle [17]. Indeed, it has been well established that somatic stem cells exist in the OSE due to the cyclical ruptured and regeneration that occurs with ovulation [31]. These stem cells are characterized by a high capacity of self-renewal and slow cycling in physiological conditions, but they exhibit high proliferative potential during wound healing and in tissue culture. Normal label-retaining OSE cells were demonstrated to exhibit stem/progenitor cell characteristics [10]. Stem cell niche of OSE is verified to locate in the hilum region of the ovary [11]. In addition, we find that M-E cells are able to maintain growth only in a 1:1 mixture of fresh and conditioned medium. The extracellular

proteins, such as Mmp2, Mmp5, Col3a1, and Wnt5b, were increased in M-E cells, suggesting conditioned medium containing extracellular proteins could promote cell proliferation. Hence, further studies on metabolomics profiling of conditioned medium may help to identify key components of early pre-neoplastic ovarian cancer.

With increased passage numbers, proliferative phenotype is paralleled with the neoplastic ability of M-I cells. But they are only identified as atypical hyperplasia. These cells recapitulate the continuum of cellular changes that represent the transition at early passage from mild to moderate at intermediate passage. The proportion of tetraploid cells increased from 10% at early to 30% at intermediate stage. Cells undergoing EMT are known to lose E-cadherin and gain Vimentin expression, resulting in tumor cell invasion and metastasis [34]. But Burkhalter et al found that E-cadherin expression is increased with malignant transformation in ovarian cancer [35]. The expression of E-cadherin and Pan-keratin, even b-catenin in the intermediate stage is the highest in the present study. In accordance with other reports [19, 24], we also found that MOSE cells exhibited both mesenchymal and epithelial markers continuously. This mixed phenotype enables the OSE cells to respond rapidly to a variety of environmental, hormonal, and stress factors, but it is also thought to contribute to the onset of neoplastic transformation by rendering the cells more susceptible to transition from an epithelial to a mesenchymal-like phenotype.

M-L cells represent the most aggressive transitional stage and display features similar to tumor cells, such as increased proliferation, and above 50% triploid and tetraploid cells. M-L cells are oncogenic transformed supported by two key evidences, enhanced capacity for anchorage-independent growth *in vitro* and rapid tumorigenic potential *in vivo*. These characteristics are associated with a continued expression of Pan-keratin, Vimentin and b-catenin and up-regulation of EMT-inducing transcription factor Snail and Slug. As we all know, EMT is a highly conserved cellular program that allows polarized, well-differentiated epithelial cells to convert to depolarized, motile mesenchymal cells. Moreover, the transient induction of EMT in large populations of cancer cells may make it possible that the generation of relatively unlimited numbers of CSCs [15, 36]. The stem cells of certain epithelial organs show many of the attributes of the mesenchymal cell state. Therefore, M-I cells displayed phenotype of both EMT alteration and stemness acquisition.

There are several characteristics of EOC which indicate that it may be a stem cell-driven disease. Such as, EOC can generate differentiated subtypes that recapitulate the histology of other normal gynecologic tissues and the high rate of chemoresistance and recurrence after successful initial treatment. In clinical and experimental studies, the high level of stem-cell markers, such as Nanog, ALDH-1, CD44, CD117, CD133 and Sox-2, were found to be associated with poor outcomes of EOC patients [30, 37-40]. CSCs contribute to the aggressive behavior of EOC [38, 41]. Our findings also suggest that acquisition of stemness is associated with malignant spontaneous transformation of OSE cells in long-term culture.

Conclusions

In conclusion, we established a model representing early, intermediate, and late stages of neoplastic transformation of ovarian surface epithelium. Alteration of EMT and acquisition of stemness are closely correlated to spontaneously oncogenic transformation of OSE cells. The model is a powerful tool for *in vitro* mechanistic studies, as well as for efficacy studies *in vivo* of both chemotherapeutic treatment regimens and chemopreventive strategies.

Abbreviations

CSCs: cancer stem-like cells; EMT: epithelial-mesenchymal transition; MOSE cells: mouse ovary surface epithelial cells; M-E: early stage of MOSE cells; M-I: intermediated stage of MOSE cells; M-L: late stage of MOSE cells.

Declarations

Ethics approval and consent to participate

The performance of the animal experiments followed the 3R principle, in order to minimize the number of animals recruited for the experiments and to reduce their burden. All animal experiment was performed according to the protocols of IACUCSU. The approval number is ECSU-201800049.

Consent for publication

Not applicable.

Availability of data and materials

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

Competing interests

The authors declare that they have no competing interests.

Funding

This study was supported by the National Natural Scientific Funding of China (grant No. 81872622, 81673151, U1832140, and 81372979), and BL is the Principle Investigator. The funding source had no role in the study design, data collection and analysis, the decision to publish, or the preparation of this manuscript.

Authors' contributions

BL conceived and designed the experiments; HZ, YG, LL, YH and PW performed the experiments; HZ and YG analyzed the data; FJ and ZZ contributed material and analysis tools; BL, ZZ and TOM K.HEI drafted

and revised the paper. All authors read and approved the manuscript

Acknowledgments

Figures

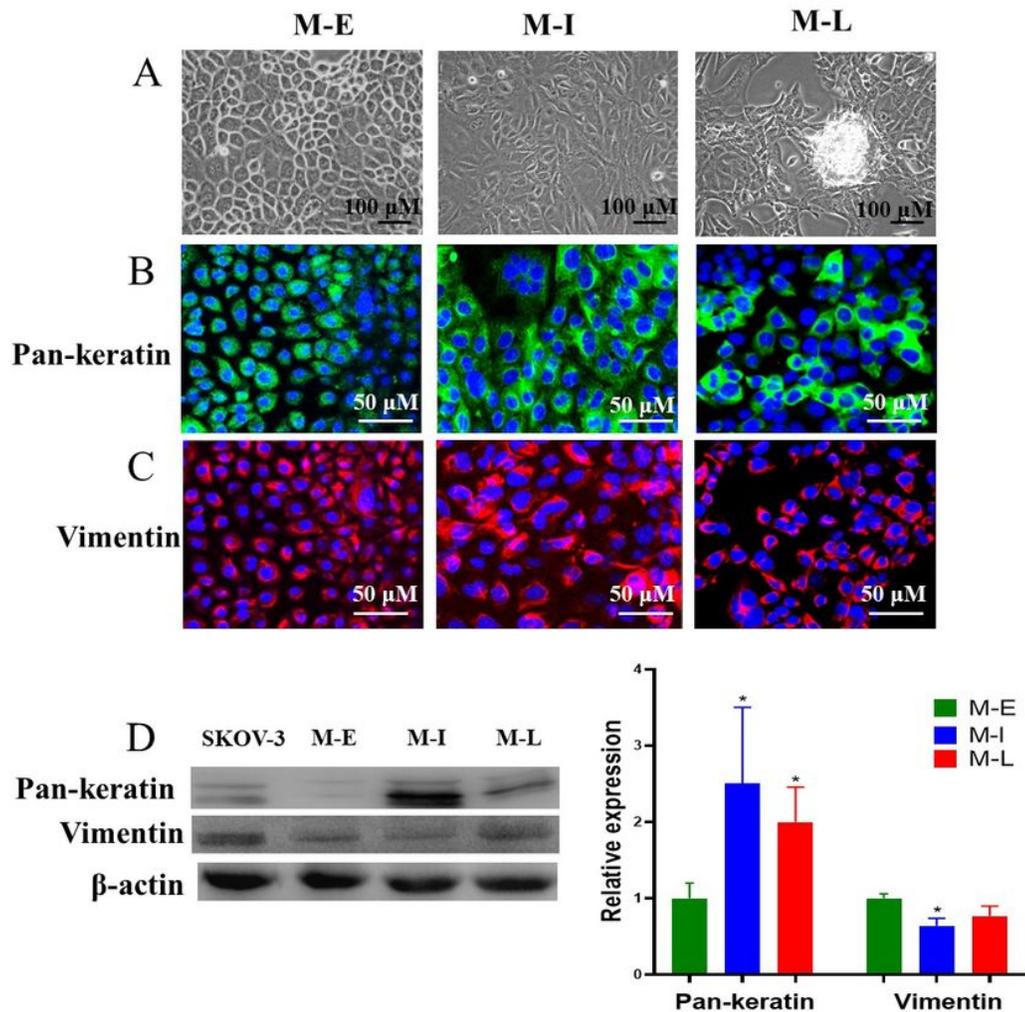

Figure 1

MOSE cells exhibit positive marker of both epithelial and mesenchymal during spontaneously malignant transformation. (A) Morphology of MOSE cells at different transitional stage in vitro. Early, intermediate and late passage MOSE cells were presented as M-E, M-I, and M-L, respectively. (B) Representative

images of MOSE cells staining with Pan-keratin (green) and DAPI (blue). (C) Representative images of MOSE cells staining with Vimentin (red) and DAPI (blue). (D) Western blotting analysis of Pan-keratin and Vimentin in M-E, M-I and M-L cells. β -actin served as a loading control. Error bars represent SEM and statistical analysis was performed using Student's test. * $P < 0.05$ compared with M-E cells.

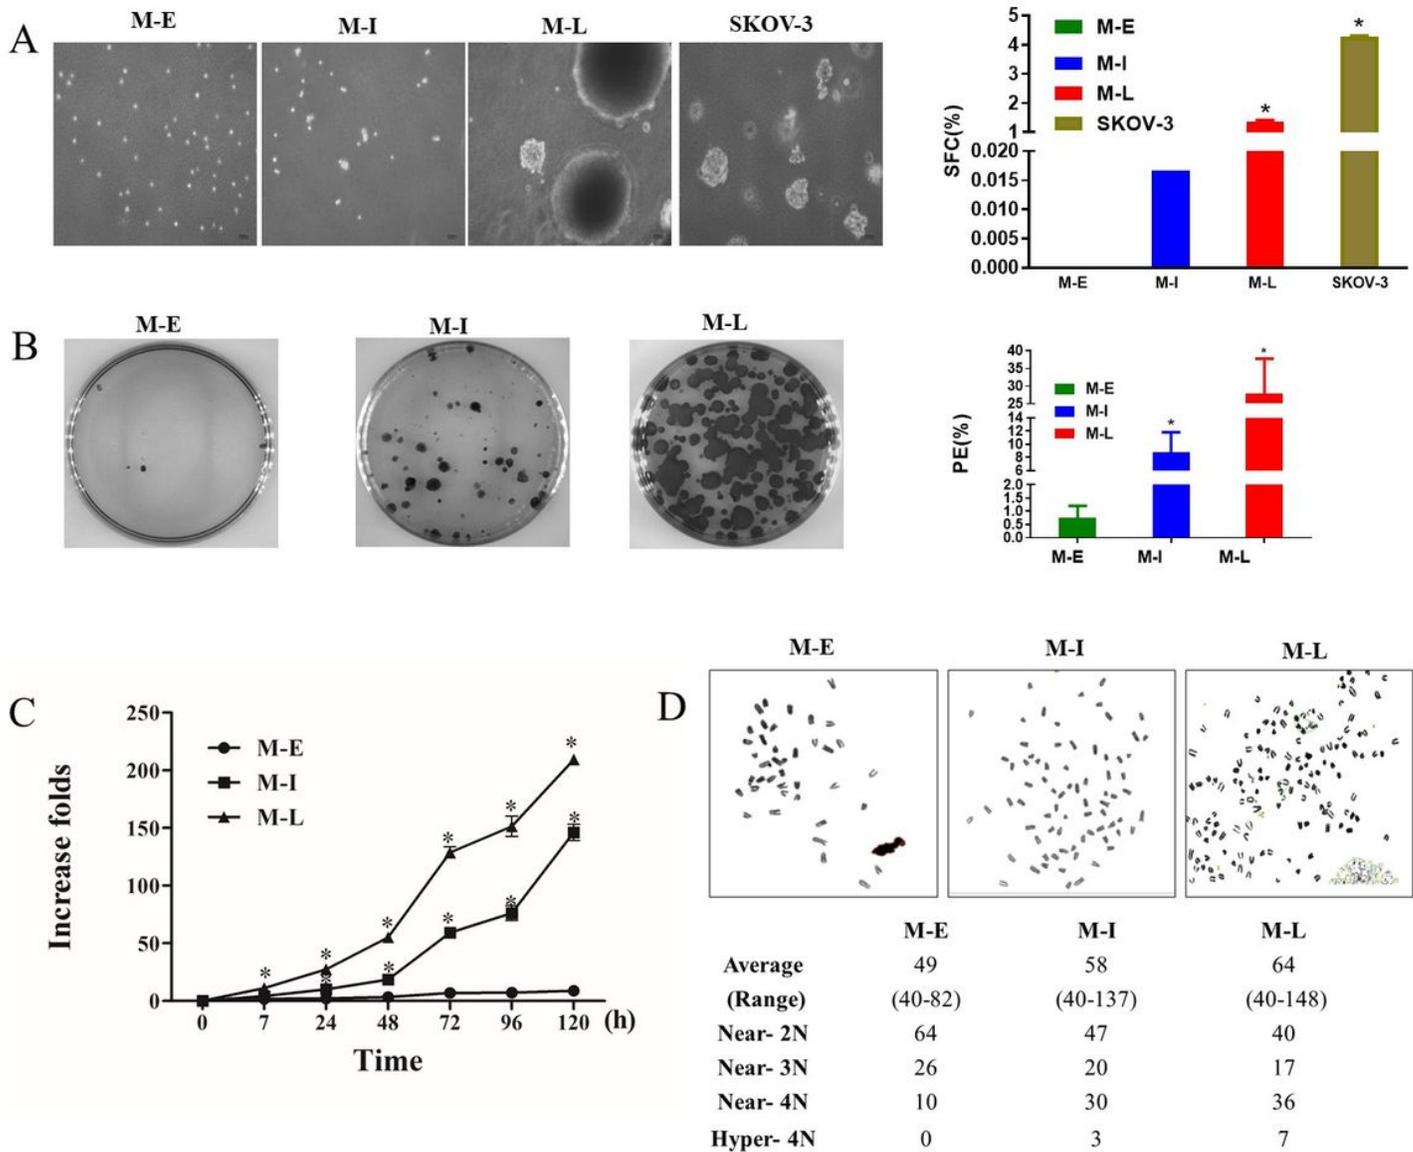

Figure 2

Proliferation ability of MOSE cells was dramatically increased with malignant transformation in vitro. (A) Colony formation in soft agar. Left: Representative images of colonies in soft agar. Right: Relative percentage of colony forming units. SKOV-3 cells were used as positive control. (B) Colony formation in plate. Left: Representative images of colonies in plate. Right: Relative plating colony efficiencies. (C) Cell proliferation rate at different transitional stage by CCK8 assay. (D) Upper: Representative karyotype of MOSE cells at different transitional stage ($\times 630$). Lower: Summary of chromosomal number analysis of

MOSE transitional stages. Error bars represent SEM and statistical analysis was performed using Student's test. * $p < 0.05$ compared with M-E cells.

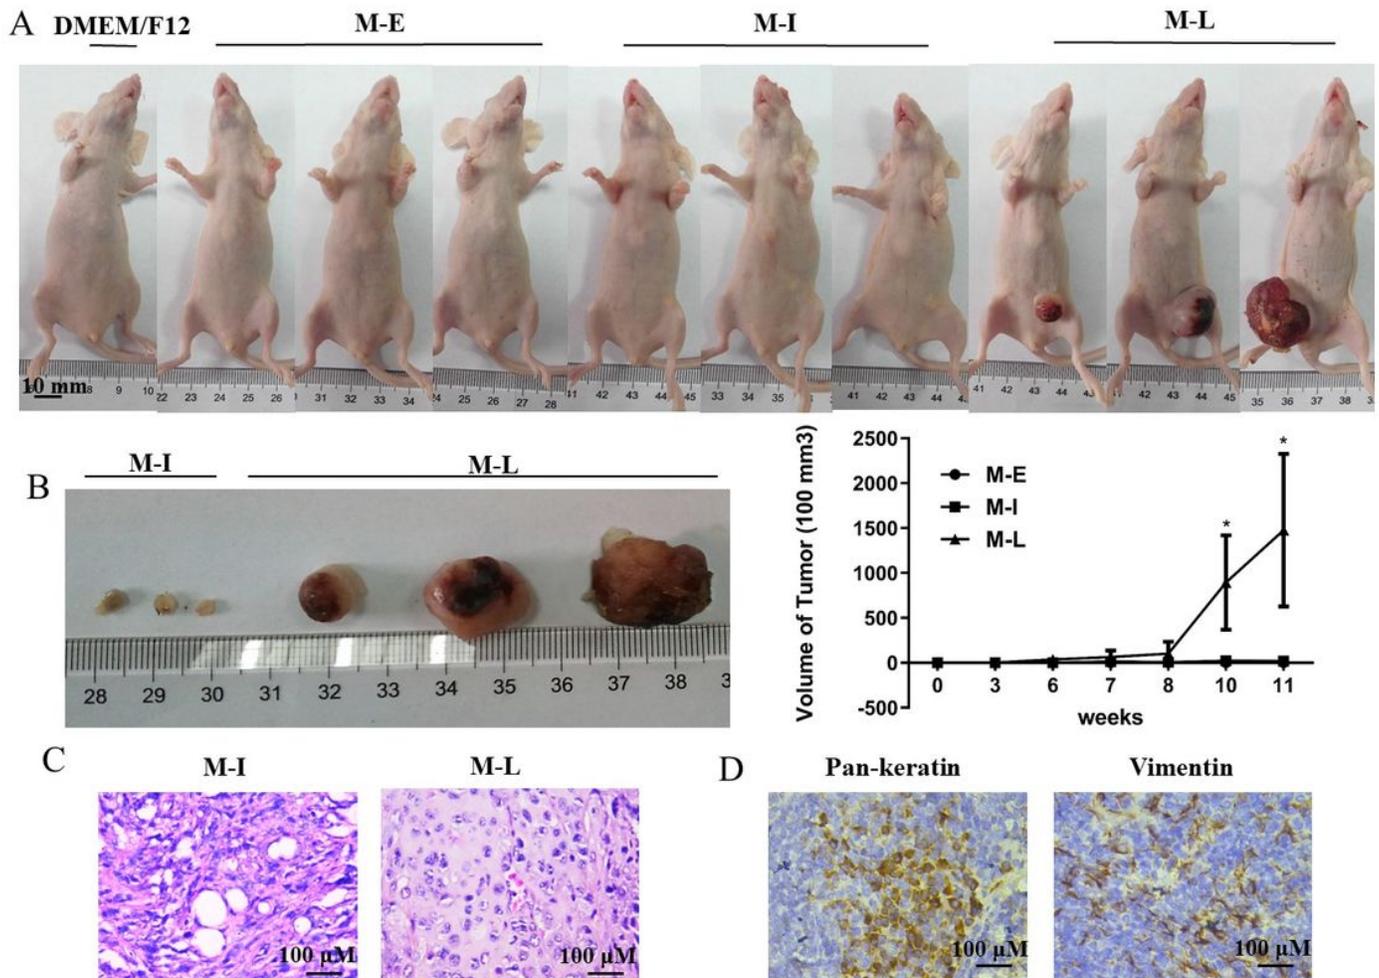

Figure 3

Tumorigenicity of MOSE cells in vivo. (A) Representative subcutaneous tumors formed by the indicated cells. DMEM/F12 was used as negative controls. (B) Tumor nodules were taken at the time of euthanasia (left), and tumor volumes were recorded at the indicated time points (right). Error bars represent SEM and statistical analysis was performed using Student's test. * $p < 0.05$ compared with M-I cells. (C) HE staining of tumor generated from M-I and M-L cells. (D) Immunohistochemistry staining of epithelial markers Pan-keratin (left) and mesenchymal markers Vimentin (right).

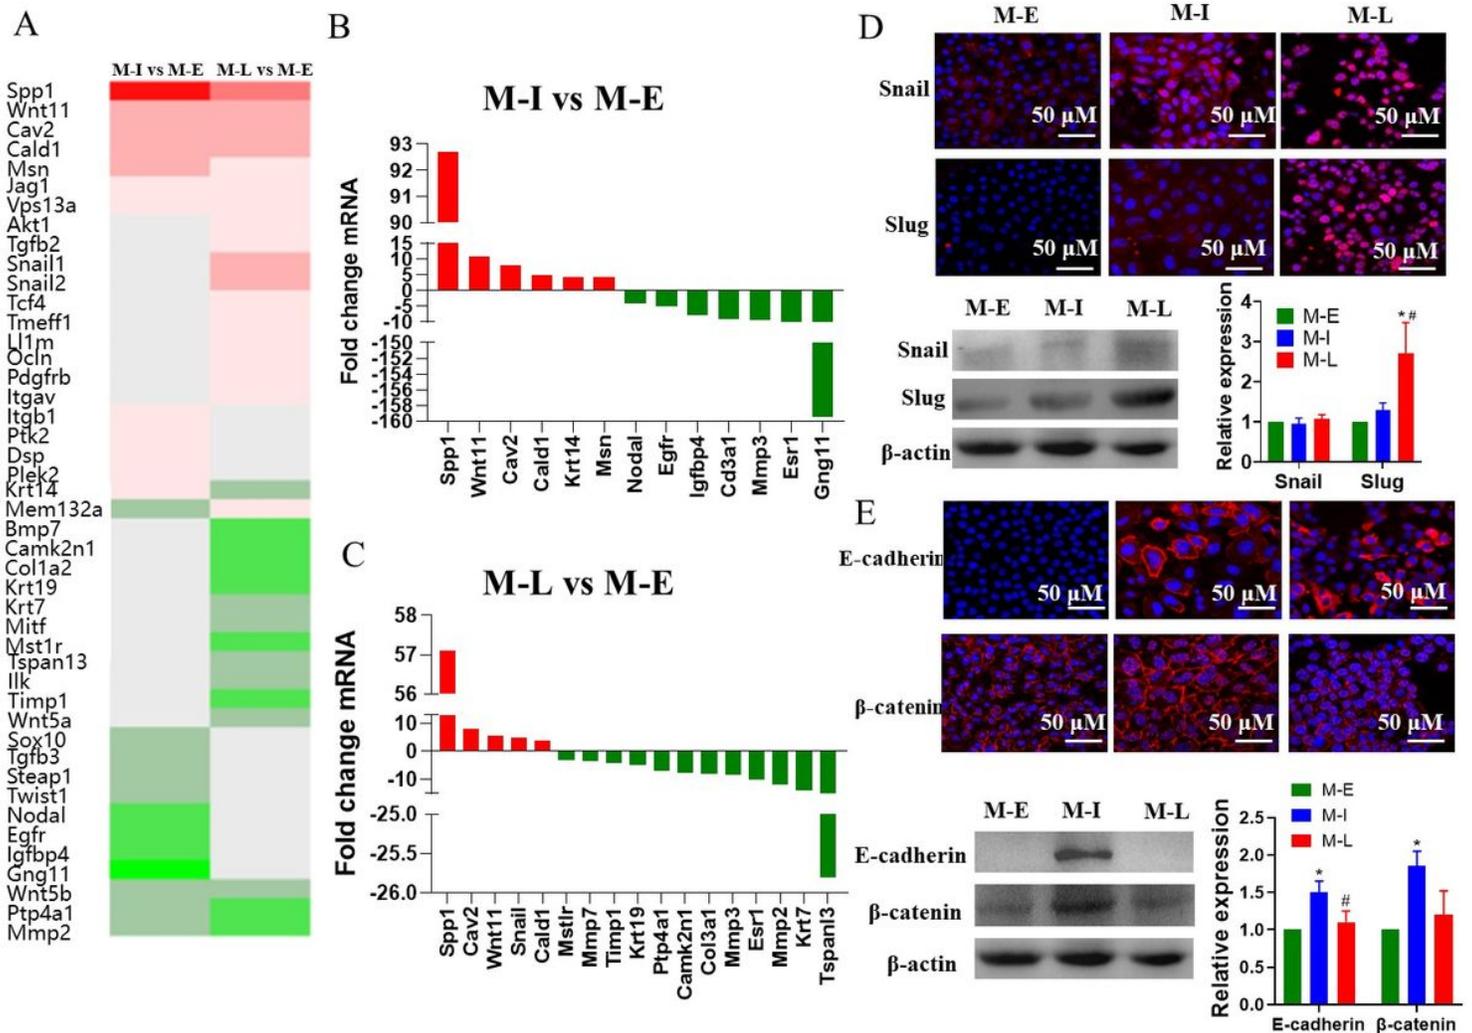

Figure 4

The alteration of EMT contributes to oncogenic transformation of MOSE cells. (A) Differential genes that were up-regulated (Red) or down-regulated (Green) by more than 3-fold. (B) Histograms depict the fold change differences in expression between M-I and M-E. (C) Histograms depict the fold change differences in expression between M-L and M-E. (D) Immunofluorescence staining and western blotting analysis of Snail and Slug of MOSE cells at different transitional stage. (E) Immunofluorescence staining and western blotting analysis of E-cadherin and β -catenin of MOSE cells at different transitional stage. Error bars represent SEM and statistical analysis was performed using Student's test. * $p < 0.05$ compared with M-E cells; # $p < 0.05$ compared with M-I cells.

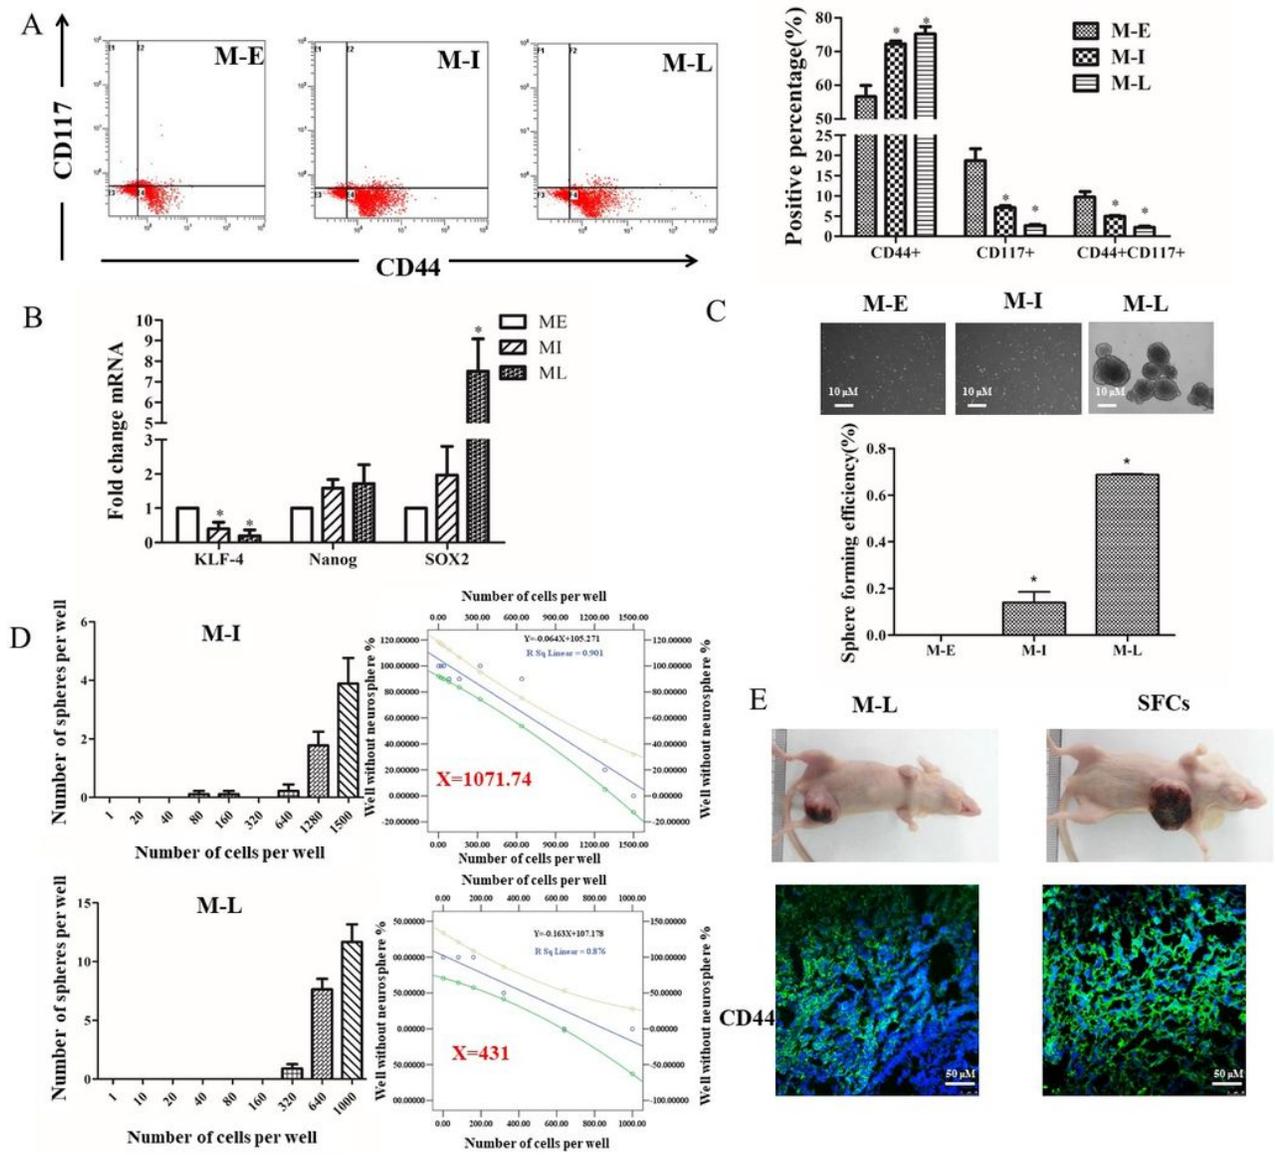

Figure 5

Figure 5

The acquisition of stemness involves in oncogenic transformation of MOSE cells. (A) Left: Flow cytometry analysis on the expression of CD44+/CD117+ stem cell markers. Right: The percentage of CD44+, CD117+ and CD44+/CD117+ cells from M-E, M-I and M-L cells (right). (B) Quantitative RT-PCR analysis of stemness-related genes expression in M-E, M-I and M-L cells. The expression of each gene was normalized to GAPDH. (C) Representative pictures (upper) and quantification (lower, means \pm SD) of sphere-forming cells (SFCs) in M-E, M-I and M-L. (D) Limiting dilution assay showed that M-L cells possessed higher capability of sphere formation than M-I cells. (E) Upper: Representative subcutaneous tumors formed by M-L and SFCs. Lower: Immunofluorescence staining of CD44 in M-L and SFCs generated tumors. Error bars represent SEM and statistical analysis was performed using Student's test. *P < 0.05 compared with M-E cells; # p < 0.05 compared with M-I cells.
