Abstract

Ongoing global warming is likely to increase the return frequency of very intense hurricanes in the North Atlantic. Here, we analyse how this frequency increase may impact on economic growth. To this end, we introduce an event-based macroeconomic growth model that allows us to assess how growth depends on the heterogeneity of hurricane impacts, by temporally resolving the economic response dynamics to individual hurricanes making landfall. We calibrate the model to hurricane impacts in the United States and find that economic growth losses scale super-linearly with the heterogeneity of hurricane impacts. We explain this by a disproportional increase of indirect losses with event severity which can lead to an incomplete recovery of the economy between consecutive intense landfall events. Based on two different methods to estimate the frequency increase of intense hurricanes, we estimate annual growth losses to increase by moderate 7% up to 146% in a 2°C world compared to the period 1980-2014. Our modelling suggests that higher insurance coverage may be a viable means to mitigate this climate change-induced increase in growth losses.

Introduction

Already in the present climate, tropical storms in the North Atlantic, called hurricanes, cause substantial economic losses in the United States (US). Between 1980 and 2019, these storms caused on average about US\$ 31 billion in direct economic losses per year, peaking at US\$ 266.5 billion in 2005 according to MunichRe's NatCatSERVICE database¹. Moreover, there is increasing empirical evidence that, in addition to these direct losses, tropical storms can substantially reduce economic growth of affected countries for more than a decade^{2;3;4}. These long-term growth impacts may have important implications for the adaptation to, and coping with, the impacts of tropical storms under global warming, since there is strong evidence that the proportion of very intense storms may increase^{5;6;7}. There are at least two mechanisms through which this increase could overcompensate a possible mild decline of the overall number of tropical storms⁵ driving up economic losses. First, the most intense storms cause dis-proportionally larger direct economic losses than smaller storms. For instance, major hurricanes of the two highest categories 4–5 on the Saffir-Simpsons scale⁸ have accounted for almost half of normalised economic damage from all hurricanes that made landfall in the US in the period 1900-2005 despite representing only about 6% of landfall events⁹. Second, an increase of the return frequency implies that, on average, there is less time for the economy to recover in between consecutive events; incomplete recovery has been identified as one main factor that may increase the vulnerabilities of the economy to climate extremes and thereby drive up losses^{10;11}.

Catastrophe insurance is discussed as a means to reduce economic vulnerabilities of the economy to extreme weather events by shortening the recovery time in the disaster aftermath^{12;13;14}, and it may thereby even promote economic growth on the macroeconomic level¹⁵. These promising findings may explain the rising popularity of multilateral climate risk insurance schemes and the G20 InsuResilience Global Partnership initiative¹⁶. However, it remains an open question whether higher insurance coverage and better insurance schemes will be sufficient to counteract climate change impacts in a warming world^{17;18}.

Progress in answering this question has been also made difficult by the limitations of state-of-the-art climate integrated assessment models (IAMs). These standard workhorses for climate policy assessments (see^{19;20} for detailed reviews of IAMs) – such as the

seminal DICE model²¹ which is used by the US government to estimate the cost of carbon emissions to society – have been criticised for not being able to appropriately account for the impacts of climate extremes^{22;23}. The main reason is that the coarse temporal resolution of most models (typically 5–10 years) simply does not allow for the representation of individual extreme weather events. In consequence, potentially important nonlinearities arising from a disproportional increase of total economic losses with impact intensity or from incomplete recovery between consecutive events cannot be resolved. In consequence, IAM-based studies usually report relatively small, or even negligible, impacts of climate extremes on the economy^{24;25} which are at odds with recent estimates in the climate econometric literature^{26;3;2}.

Main

Here, we first study how the heterogeneity of US hurricane impacts has affected economic growth in the period 1980–2014. We then project increases in growth losses that would arise in a 2°C world from changes in the return frequencies of the storms and associated changes in storm number and impact heterogeneity. Since there is substantial uncertainty on how the return frequencies of hurricanes will change with global warming, and the magnitude of the effect strongly depends on the underlying methodology used to estimate this change⁵, we consider two different approaches at both ends of the uncertainty range. In addition, we assess the efficacy and limits of disaster insurance in mitigating the climate change-induced increase in growth losses. To this end, we build a simple – and transparent – event-based neoclassical growth model for a national economy. The model accounts for losses to the stock of physical assets that result from individual landfall events. Reconstruction investments can be capped in the disaster aftermath to describe inefficiencies slowing down the economic recovery such as scarcity of trained labour and building materials as well as inefficiencies due to destroyed infrastructure and supply chain interruptions²⁷. Further, we integrate a basic non-profit insurance scheme providing contingency funds for reconstruction of insured assets in the disaster aftermath. With a weekly time step, the model is able to resolve the economic response dynamics to individual landfall events, and to therefore capture non-linear loss amplifications that may arise from individual high intensity or *consecutive* events. Following ref.¹⁰, we define the

latter as subsequent loss events that do not leave enough time in between for the economy to recover. In the standard calibration of the model, the insurance ratio is set to 50% the average ratio of insured losses in the US between 1980 and 2014 according to the NatcatSERVICE database¹ and reconstruction investments are capped to 0.2% of weekly output following ref.²⁷. This model calibration allows us to obtain average annual output growth losses that are comparable to those reported in the recent climate econometric literature^{2,4} when driving the model with the direct asset losses of the 88 hurricanes that made landfall in the US in the period 1980–2014 according to the NatCatSERVICE database¹.

Insurance accelerates economic recovery

To illustrate the interplay of insurance payouts and limits of reconstruction investments, we first study the economic recovery dynamics in the aftermath of an individual storm that destroys 1% of the physical capital stock in month 3 (Fig. 1A). Besides the “realistic” standard calibration of the model (or scenario) (green full lines), we consider two limiting scenarios, one without insurance (red lines) and one with full insurance coverage of all losses (blue lines). Further, to test the sensitivity of the model with regard to the construction investment cap, we consider a 1% reconstruction investment cap (dashed lines) in addition to the 0.2% reconstruction investment cap (solid lines) and contrast both to a limiting case where all available investments (difference between output and savings) can be used for reconstruction (“no investment cap”, dotted lines) (Fig. 1B). Since insurance premiums depend on insurance coverage, each growth trajectory is normalised to the balanced growth path of an unperturbed economy with the same insurance premium. To account for delays in insurance payouts, we fit data on cumulative insurance payouts of the Reinsurance Association of America²⁸ indicating that 60% (90%) of the insured losses are paid out after one (three) year(s) with a sigmoidal function (see Methods for details). The resulting weekly payouts are shown in the inset of Fig. 1B.

Generally, the recovery of the economy can be divided into a first phase of rapid reconstruction of destroyed capital, and a second phase, where the economy slowly approaches the balanced growth path of the unperturbed system. The recovery speed in the first phase is reduced when the reconstruction investment cap is lowered. For the

Fig. 1. The impact of insurance and reconstruction investment on the economic recovery dynamics in the aftermath of an individual hurricane with landfall. Response dynamics in the aftermath of a 1% shock to the capital stock with with no (red), 50% (green), and full (blue) insurance coverage, for scenarios where maximum weekly reconstruction investment is not limited (dotted lines) as well as limited to 0.2% (solid lines) and 1% (dashed lines) of weekly output, respectively. **A** Time series of weekly output relative to the output of an unperturbed economy on the balanced growth path. **B** Time series of weekly reconstruction investment (in % of weekly output) and weekly insurance payout (in % of direct asset losses to the capital stock, inset). **C** Cumulative output losses until full recovery of production capacity as a function of the direct asset losses (both in terms of annual output in the year before the landfall). Vertical grey lines indicate the asset losses caused by the historical major hurricanes Sandy, Andrew, and Katrina according to the NatCatSERVICE database¹.

scenario with the lowest reconstruction investment cap and no insurance, the cap even limits the recovery dynamics in the slow second phase (red solid lines in Fig. 1A). In line with empirical findings, recovery speed increases with insurance coverage for two reasons^{29;30}. First, since insurance provides additional financial means for reconstruction, the reconstruction investment cap can be temporarily exceeded. This accelerates the recovery process especially in the first reconstruction phase. Second, the larger the insurance coverage the lower is the share of the output that has to be reinvested in reconstruction efforts. In consequence, more output can instead be invested in new capital. This fosters output growth especially in the slow recovery phase. Except in the limiting, overly optimistic, case of full insurance coverage and no reconstruction investment cap, cumulative output losses increase super-linearly with the size of the direct asset losses, i.e., *indirect losses* increase with shock size (Fig. 1C). In consequence, in the aftermath of intense hurricane shocks it can take multiple months or even years for the economy to recovery. For instance, in the standard scenario, it takes more than 5 months for the production capacity to recover after the major hurricanes Andrew and Sandy that struck Florida and Louisiana in 1992 and New York and New Jersey in 2012, respectively, both causing asset losses equivalent to about 0.4% of the US's annual output in the years of landfall, respectively (grey vertical lines in Fig. 1C). Further, our modelling suggests that in the aftermath of the largest historical loss event, the landfall of hurricane Katrina in New Orleans in 2005, that caused asset losses equivalent to 0.8% of the US's annual output in this year, it took more than one year and a half for the production capacity to recover.

Growth losses increase with shock heterogeneity

Next, we study how the economic response dynamics depends upon the heterogeneity of hurricane shocks (Fig. 2). For that, we assume that i) landfall events are Poisson³¹ distributed within the US hurricane season (June–November) and ii) direct asset losses (relative to the growth domestic product of the years the hurricanes made landfall) are log-normally distributed³² (see supplementary Fig. S5 for a log-normal fit of the data). In the remainder of this paper, we will refer to the distribution of relative asset losses as *shock distribution*. As detailed in Sec. A.3 of the Methods, drawing from this shock distribution allows us to generate synthetic time series of asset losses with defined length,

Fig. 2. Recovery dynamics of production capacity in dependence of hurricane shock heterogeneity. Economic impacts of hurricane shocks for a period of 35 years. The heterogeneity of shocks increases from **A** to **C**. Hurricane number and relative cumulative asset losses are fixed to the 88 hurricanes that reportedly made landfall in the United States in the period 1980-2014 and caused 3.24% of cumulative asset losses (relative to the growth domestic product of the years the hurricanes made landfall) according to the NatCatSERVICE database¹. **B** depicts the impacts of the observed historical time series of hurricanes with landfall. **Left panel:** Exemplary time series of available production capacity (in % of full production capacity (grey horizontal lines)). Periods of reduced capacity in the disaster aftermaths are marked in red and shocks are marked by grey dots with the size of the dots indicating the shock size. Vertical grey lines indicate major historical landfall events in **B**. **Right panel:** Lorenz curves to illustrate the heterogeneity of the shock distribution. Red lines indicate the cumulative share of production capacity losses as a function of the cumulative share of the shocks. Grey diagonal lines indicate the Lorenz curves for equally distributed shocks. The Gini index $G \equiv \frac{L_e - L_i}{L_e}$ as measure for shock heterogeneity is determined by the ratio of the areas under the red (L_e , light blue shading) and blue lines (L_i , dark blue shading). **D** Mean cumulative available production capacity (in % of the production capacity of unperturbed system) as a function of the Gini index. Red dots and grey shaded areas indicate the values of the Gini index obtained for the runs in **A–C** and the 16.7-83.3 percentile confidence interval, respectively. The grey vertical line indicates the median Gini index of the historical shock distribution (see Methods). Other parameters: Insurance coverage 50%; reconstruction investment cap 0.2% of weekly output.

event number, and value for the cumulative relative asset losses. To isolate the impact of shock heterogeneity, we then vary the heterogeneity of the asset losses – measured by the Gini index (G) of the event distribution – but keep the number of hurricanes with landfall (88) (and thus average hurricane return frequency) as well as relative cumulative direct asset losses (3.24% of cumulative output) at their values reported in the NatCatSERVICE database¹ for the study period 1980–2014 (35 years). For a nearly homogeneous shock distribution ($G = 0.018$), asset losses (grey circles in (Fig. 2A–C)), asset losses are relatively small and production capacity can mostly recover between loss events and stays close to the one of the unperturbed system for the whole study period (Fig. 2A). For higher values of the Gini index, we obtain many small but few high intensity loss events. Since cumulative output losses increase dis-proportionally with event intensity (cf. Fig. 1C), also the risk for incomplete recovery between events increases for higher values of the Gini index (cf. Fig. 2B and C for $G = 0.83$ and $G = 0.87$). For instance, when driving the model with the historical sequence of landfall events, we find that the US economy may not have recovered in between the major hurricanes Katrina and Sandy (Fig. 2B).

To gain a systematic understanding on how production capacity depends upon shock heterogeneity, we study the cumulative production capacity over 35 years as a function of shock heterogeneity. For a given shock distribution, cumulative production capacity in general differs between event realisations due to differences in the timing and the size of the shocks. To account for this uncertainty, we generate a large ensembles of 20,000 realisation for each shock distribution. The cumulative production capacity is then plotted as a function of the median Gini index as obtained across all realisations (see Sec. A.2 of Methods) (Fig. 2D). (Note that values of the Gini index for individual realisations may substantially deviate from the median Gini index. For instance, the Gini index for the observed historical storm sequence ($G = 0.83$) is substantially higher than the median value of the Gini index across all realisations for the historical storm distribution ($G = 0.71$) (compare red dot to vertical grey line in Fig. 2D).) We find that the available production capacity reduces super-linearly with increasing shock heterogeneity. The reduction is strongest in the high heterogeneity range to the right of the median Gini index for the historical period (grey line in Fig. 2D), where incomplete recovery becomes more likely.

Similarly, economic growth declines super-linearly with increasing shock heterogeneity (Fig. 3). Consider besides the standard scenario with a 0.2% reconstruction investment

cap and 50% insurance coverage (red line in Fig. 3B) again scenarios with a 1% and no investment cap (green and blue lines in Fig. 3) as well as the limiting cases of no and complete insurance (Fig. 3A and Fig. 3C), we find that the dependence of economic growth on shock heterogeneity increases when i) the reconstruction investment cap and ii) the insurance coverage is lowered.

Fig. 3. Impact of hurricane shock heterogeneity on annual output growth rate. Median annual growth rate change of the economy under hurricane shocks relative to the growth rate of the corresponding unperturbed economy, as a function of shock heterogeneity – measured by the Gini index – for no (A), half (B), and full (C) insurance coverage. Blue, green, and red lines depict median growth rate changes for scenarios where reconstruction investment is not limited, limited to 0.2%, and 1% of weekly output, respectively; shaded areas mark the corresponding 16.7-83.3 percentile confidence intervals. The grey vertical line indicates the median Gini index of the historical distribution of relative direct asset losses.

For low values of the investment cap, the growth reduction with increasing shock heterogeneity can be quite substantial. For instance, for the standard scenario, annual growth losses increase by more than 16% from 0.0238 percentage points (p.p.) for the lowest to 0.0275 p.p. for the highest value of the Gini index (red line in Fig. 3B). While these growth rate reductions may appear small, they imply that for the highest value of the Gini index output losses accumulate over three and a half decade to 16,218 US\$ per-capita, an additional 2,196 US\$ per-capita compared to the lowest value of the Gini index. The dependence of growth on shock heterogeneity can again be understood by

the disproportional increase of indirect losses with shock intensity making incomplete recovery between events more likely with increasing Gini index (cf. Fig. 1A). In line with this reasoning, we find that, in the scenario without construction investment cap, where the recovery time is substantially shorter than in the scenarios with caps (cf. Fig. 1), growth losses are nearly independent of the Gini index.

Further, for each fixed level of shock heterogeneity, growth losses decrease with increasing insurance coverage which can be understood as follows: Insurance provides additional financial means for reconstruction and thereby mitigates the impact of shocks that are large compared to the reconstruction investment cap by reducing the recovery time and therefore suppressing incomplete recovery. For instance, for the standard scenario and the median Gini index of the historical period (grey vertical line in Fig. 3), output losses accumulate over three and a half decades to 14,904 US\$ per-capita. They are therefore, on average 832 US\$ per-capita and 1,121 US\$ per-capita higher than for the corresponding scenarios with a 1% and without reconstruction investment cap, respectively.

The greatest benefit of insurance is, however, that it strongly mitigates the magnitude of growth losses. For the median Gini index of the historical period and the lowest investment cap, hurricanes reduce annual growth on average by 0.048 p.p. in the uninsured scenario. These losses are already roughly halved to 0.025 p.p. for the standard scenario with 50% insurance coverage and reduced by a magnitude larger than ten to 0.0045 p.p. in the fully insured scenario. Accordingly, output losses accumulate over three and a half decade decrease from 28,807 US\$, over 14,904 US\$, to 2,746 US\$ per-capita. To set all these numbers into context, it is important to keep in mind that our model, by construction, computes growth losses borne by the US in total. Local growth losses in the affected counties may be much larger.

Better insurance coverage can help mitigate climate change-induced growth losses

We estimate the growth impacts of hurricanes in a 2°C world corresponding to an increase of about 1.1°C relative to the studied historical period. To account for the substantial uncertainty on how climate change will impact on hurricane climatology, we employ two different approaches estimating climate change-induced changes in the return frequencies of hurricanes, one at the lower and one at the upper end of the impacts reported in the

recent literature⁵. Both approaches consistently predict an increase of the proportion of very intense storms, though the magnitude of this change – and in consequence the resulting changes to direct asset losses – differs substantially between the two approaches. Importantly, in contrast to the last section, where only the heterogeneity of events was mutable, these climate change-induced frequency increases may additionally translate into changes of the distribution of direct asset losses with respect to i) the number of hurricanes and ii) the cumulative direct asset losses during the study period (Fig. 4) (see Methods for details). Knutsen et al. report a *moderate* increase of the return frequency of the most

Fig. 4. Visualisation of climate change-induced shifts of the hurricane shock distribution. Under global warming, the historical distribution of the direct asset losses caused by the $N_s = 88$ historical hurricanes that made landfall in the US in the 35-years period from 1980 to 2014 (black filled circle) according to the Nat-CatSERVICE database¹ is projected to change along three dimension: i) the median shock heterogeneity measured by the Gini index (x-axis), ii) the number of landfalls for a 35 years period (y-axis) and iii) the median cumulative direct asset losses (size of circles). Blue and red filled circles indicate estimates for a +2°C world (above pre-industrial levels) based on Grinsted et al.⁶ and Knutsen et al.⁷, respectively. The numbers in the circles refer to the median cumulative relative asset losses for a 35 years period (see Methods for details).

intense (Cat. 4-5) hurricanes by 45% but a reduction of the overall number of hurricanes (of all categories) by 22%, which the authors derive from changes in the maximum lifetime wind speeds of the storms obtained from dynamical down-scaled global circulation model

runs⁷ (“wind speed-based” estimate). In contrast, Grinsted et al. use observational storm surge data and estimate a *considerable* increase of relative return frequencies ranging from 1.4 fold for storms with a small surge index to a 6.4 fold for the most intense storms⁶ (“surge-based” estimate). The authors’ statistical analyses cannot distinguish whether this frequency increase is caused by an overall increase in the number of storms or merely implies a shift of the distribution of storm surges to higher intensity events. However, since there is relatively good agreement in the literature that the average number of hurricane per season will not strongly change with global warming⁵, in our derivation of future direct asset losses according to Grinsted’s surge-based estimate, we assume that the number of storms does not change compared to the historical study period (see Methods for details).

For both, the surge- and wind speed-based estimates, we obtain a moderate increase of shock heterogeneity with the median Gini index increasing from its historical value of 0.71 to 0.77 and 0.78, respectively. For the former, the hurricane number (88) remains unchanged compared to the historical period whereas it decreases to 69 for the latter. Further, the estimated cumulative relative asset losses over 35 years increase only moderately from 3.24% for the historical period to 3.75% for the wind speed-based estimate but more than double (7.25%) for the surge-based estimate. In terms of median annual growth losses, we obtain a moderate increase by 7% compared to the historical standard scenario for the wind field-based estimate but a strong increase by 146% for the storm surge-based estimate (Fig. 5A). The reason is that for the former the additional growth losses due to the increases of shock heterogeneity and cumulative direct asset losses are partially compensated by the reduction of growth losses due to the reduced absolute number of hurricanes; whereas for the latter the increases of shock heterogeneity, cumulative direct asset losses, and hurricane number all enhance growth losses. Since we always consider growth losses relative to a baseline scenario with the same reconstruction investment cap (and insurance coverage), these findings are robust with regard to changes in the reconstruction investment cap (cf. Fig. 5B and Fig. 5C).

We finally address the question whether an increase in insurance coverage would be sufficient to compensate for the additional global warming-induced growth losses. We find that, to this end, the historical insurance coverage of 50% would have to be substantially raised from 50% to 84% according to the surge-based estimate, whereas a moderate increase to 58% would suffice according to the wind field-based estimate for the standard

Fig. 5. Projected impacts of hurricanes on economic growth in a 2°C world and the effectiveness of insurance as coping strategy. Annual growth losses (relative to the corresponding unperturbed economies evolving on the balanced growth paths) as obtained for the historical shock distribution (50% insurance coverage, period 1980-2014; 1st column) and for +2°C warming above pre-industrial levels (2nd through 5th column) for reconstruction investment caps of 0.2% (**A**, standard scenario), 1% (**B**) and without reconstruction investment cap (**C**). Climate change projections of growth losses are derived from two different methods to estimate climate change-induced changes in the return frequencies of hurricanes by Grinsted et al.⁶ and Knutsen et al.⁷ (50% insurance coverage, 2nd and 4th columns, respectively). Additionally, for both estimates the insurance coverage that would be necessary to reduce growth losses to the historical level are shown (3rd and 5th column). Orange lines, boxes, and whiskers indicate median loss estimates as well as the 25th-75th and 5th-95th percentile ranges, respectively.

scenario (cf. columns 2 and 3 and columns 4 and 5 in Fig. 5, respectively). Again, these findings are fairly robust with regard to different values of the construction investment cap.

Discussion

These numbers suggest that a better insurance coverage could indeed be a viable means to compensate for climate change-induced increases in tropical storm-related losses, even in the absence of other adaptation measures. However, we caution that our simulations may underestimate climate change-induced growth losses by hurricanes for several reasons. First, we only consider a strong climate change mitigation scenario where the global community manages to limit global warming to +2°C above pre-industrial levels. Our approach does not easily allow to extrapolate losses to higher levels of warming, since it is not clear from the underlying studies how return frequencies will scale at higher levels of warming. Equally important, our estimates of climate-induced changes in direct asset losses are based on estimates for the changes in the return frequencies of the storms only; other potential channels through which climate change may impact on the economic losses caused by tropical storms, such as increasing storm surge risk due to sea level rise^{33;34}, and stronger precipitation associated with hurricanes³⁵ are neglected. Accounting for these additional drivers would most likely increase future economic losses^{36;37}. Further, using a simple macroeconomic growth model with only one homogeneous output good, our analysis cannot provide information on the recovery dynamics of individual sectors and may therefore underestimate delays arising from the scarcity of intermediate goods from strongly affected sectors needed for production in other sectors and the associated scarcity-induced price inflation in the disaster aftermath. In consequence, we may underestimate recovery costs^{38;39;40} and, in consequence, growth losses. Finally, we assume a non-profit insurance scheme without any handling charges and the potential insurability of all disaster losses. This might provide an over-optimistic assessment of the efficacy of insurance in mitigating disaster losses.

Our research stresses the importance of non-linear economic responses to consecutive extreme weather events. In particular, our results suggest that only by i) resolving the response to individual events, and by ii) accounting for a realistic timing of the events (e.g., accounting for the hurricane season), it is possible to estimate the full economic impact of

extreme events²². Further, these findings are key to assess the efficacy of adaptation and coping strategies. For instance, in our study the limited pace of insurance payouts delays reconstruction efforts in the disaster aftermath, but a similar reasoning holds for other adaptation measures such as sea walls or levees, which, once breached, may take months or even years to be reconstructed⁴¹. Thus, temporally resolving the economic recovery phase is critical for the assessment and comparison of disaster response measures. This aspect becomes especially important since extreme weather events are projected to intensify and become more frequent with global warming, at least on a regional level⁴². In this regard, our findings may also encourage the climate integrated assessment modelling community to consider new approaches allowing to go beyond smooth damage functions translating changes in global mean temperature into aggregate output losses. As shown here, this common approach may underestimate the economic repercussions of extreme weather events since it neglects potentially important non-linearities in the economic response such as the disproportional increases of indirect losses with impact intensity or the case of incomplete recovery²². This may also explain the discrepancy between the loss estimates reported in the recent climate econometrics literature and the estimates of climate integrated assessment models.

While our estimates on how climate change may impact on economic losses caused by hurricanes in the US are subject to several sources of uncertainty, they nonetheless show that the mitigating effect of increased insurance coverage is of the same order of magnitude as the climate change-induced loss increase; insurance can therefore be an important building block of future climate change adaptation strategies. However, it most likely has to be complemented with other measures to build resilience to extreme weather events such as investments into better housing standards and resilient infrastructure^{43;44} or coping strategies such as managed retreat^{45;46}.

A Methods

A.1 Modeling approach

As the standard neoclassical Solow-Swan growth model for a closed economy⁴⁷, our model InGroCIIM (Insured Growth under Climate Impacts) describes the growth of a per-capita stock of physical capital k for a unique indistinguishable good under investments and capital depreciation. Here, we neglect changes in labour market and population growth as drivers of capital growth. In extension to the standard model, we account for a non-profit insurance scheme and obtain two coupled differential equations for k and the per-capita capital stock of the insurance k_I reading

$$\dot{A}(t) = \Lambda A(t), \quad (1a)$$

$$\dot{k}(t) = sy(t) - [\delta + r_I] k(t) + F_I(t), \quad (1b)$$

$$\dot{k}_I(t) = r_I k(t) - F_I(t). \quad (1c)$$

Here, $(\dot{\cdot})$ denotes the derivative with respect to time t . We assume that total factor productivity (TFP) A grows exponentially with trend growth rate Λ , and s , y , and δ denote savings rate, production function, and depreciation rate of capital, respectively. The insurance premium $r_I \equiv r_I(r_c)$ depends on the economy's insurance coverage r_c , and $F_I(t)$ denotes the insurance payouts in the disaster aftermaths. Both terms are detailed below. Further, we assume that the production process can be described by a Cobb-Douglas production function $y(t) \equiv A(t)k(t)^\alpha$, where $\alpha \in (0, 1]$ denotes the capital share of income. We model the impact of extreme weather events as shocks to the capital stock. Following²⁷, we describe the economic recovery in the disaster aftermath as the superposition of two different mechanisms: i) a fast reconstruction process of the damaged capital and ii) the comparably slow growth of the capital stock due to technological development. To this end, we write the capital stock as the product of the fraction of remaining production capacity $\tilde{\zeta}(t) \in [0, 1]$ and a “potential capital stock” k_p ,

$$k(t) \equiv \tilde{\zeta}(t)k_p(t). \quad (2)$$

The Cobb-Douglas production function is derived from the assumption that the process of capital accumulation is optimal and the last unit of capital added is the least productive⁴⁸.

337 However, it appears unlikely that a disaster strikes in such a way that it “de-constructs” the
 338 capital in the same optimal way, starting with the least productive unit, and this method is
 339 likely to underestimate direct production losses (see discussion in⁴⁹ for details). Following
 340 previous works^{27;50;49}, we therefore assume that a shock does not merely destroy the
 341 least efficient capital, but equally affects all “productivity layers” of capital. For that, we may
 342 write y as a function of $\tilde{\zeta}$ and k_p ,

$$343 \quad y(t) \equiv y(\tilde{\zeta}(t), k_p(t)) = \tilde{\zeta}(t) A (k_p(t))^\alpha. \quad (3)$$

Noteworthy, this implies that at the time of the shock t_s , y reads

$$y(t_s) = \tilde{\zeta}(t_s) \lim_{t \nearrow t_s} [y(t)] = \tilde{\zeta}(t_s) A (k_p(t_s))^\alpha,$$

344 where $\tilde{\zeta}(t_s) < 1$, and $k_p(t_s)$ represents the pre-disaster value of the capital stock. Thus,
 345 production is reduced by the same factor $1 - \tilde{\zeta}(t)$ as the capital stock, i.e, direct asset
 346 losses equal direct production losses, and the marginal productivity of capital remains
 347 unchanged.

348 To derive the dynamical equations for k_p and $\tilde{\zeta}$, we first decompose total investment $I(t)$
 349 into the sum of two different investment channels: short-term reconstruction investments
 350 $I_{\tilde{\zeta}}(t)$, and regular investments increasing production capacity $I_k(t)$,

$$351 \quad I(t) \equiv sy(t) + F_I(t) = I_k(t) + I_{\tilde{\zeta}}(t). \quad (4)$$

By employing Eqs. (2), (3) and (4), we may then rewrite the dynamical equation for the
 capital stock (1b) as

$$\left(\tilde{\zeta}(t) k_p(t) \right) = \dot{\tilde{\zeta}}(t) k_p(t) + \tilde{\zeta}(t) \dot{k}_p(t) \quad (5a)$$

$$= I_k(t) + I_{\tilde{\zeta}} - [\delta + r_I] \tilde{\zeta}(t) k_p(t). \quad (5b)$$

By comparing the right-hand sides of Eqs. (5a) and (5b), we obtain the dynamical equations
 for k_p and $\tilde{\zeta}$ as

$$\dot{k}_p(t) = \frac{I_k(t)}{\tilde{\zeta}(t)} - [\delta + r_I] k_p(t), \quad (6a)$$

$$\dot{\tilde{\zeta}}(t) = \frac{I_{\tilde{\zeta}}(t)}{k_p(t)}. \quad (6b)$$

Next, we derive an expression for $I_{\xi}(t)$ which then permits us to calculate I_k from Eq. (4). To this end, we have to make four assumptions: First, we assume that reconstruction investments yield higher returns compared to investments in the potential capital stock and are therefore prioritised. Second, we assume that reconstruction efforts are limited by short-term constraints such as a lack of skilled labour or reconstruction materials, which may significantly slow down the economic recovery. In consequence, only a fraction $f_{\max} \in [0, 1]$ of the output available for investment $sy(t)$ can be used to finance reconstruction; the actual value of the investment cap $f_{\max}$ depends upon the economy under consideration⁵⁰. Third, we assume that reconstruction efforts cease when the capital stock equals the potential capital stock, no overshoot is possible. Fourth, we assume that the insurance primarily finances reconstruction efforts. In the presence of insurance, the investment cap may be temporally exceeded since the insurance provides additional financial means. This assumption is motivated by empirical findings that higher insurance coverage can lead to a faster economic recovery^{29;30}. However, if reconstruction is completed before all of the insured capital is reimbursed, the remaining insurance payout will be invested into the potential capital stock. With these assumption, we may express $I_{\xi}(t)$ as

$$I_{\xi}(t) \equiv \begin{cases} 0 & \xi(t) = 1, \\ \min [\min [f_{\max}, s] y(t) + F_I(t), I_r(t)] & \xi(t) < 1, \end{cases}$$

where $I_r(t) \equiv (1 - \xi(t))k_p(t)$ is the investment needed to reconstruct the capital stock in the present time step.

A.1.1 Insurance payout dynamics

Observational data of insurance payouts of the Reinsurance Association of America²⁸ reveal that the reimbursement of insured losses $f_I(t)$ can spread over several years; 60% (90%) of the insured values are reimbursed with in one (three) year(s). This may significantly delay the reconstruction process. We describe the cumulative insurance payouts with a sigmoidal function,

$$f_I(t - t_s; r_c \Delta_s k_p(t_s)) \equiv r_c \Delta_s k_p(t_s) \beta \frac{\left(\frac{t-t_s}{\tau_I}\right)^{\beta-1} (a-1) \exp\left[-\left(\frac{t-t_s}{\tau_I}\right)^{\beta}\right]}{\tau_I \left(1 + (a-1) \exp\left[-\left(\frac{t-t_s}{\tau_I}\right)^{\beta}\right]\right)^2}, \quad \forall t > t_s.$$

Here, t_s denotes the time of the shock, the insured losses are given by the product of the insurance coverage r_c , the asset loss Δ_s at time t_s relative to the pre-shock potential capital stock $k_p(t_s)$ ¹. The three parameters a , τ_l and β ²⁸ are specified in Tbl. 1 (see supplementary Fig. S2 for a fit of the observational data). The cumulative insurance payout in response to multiple successive asset losses $\{\Delta_{s_i}\}_i$ at times $\{t_{s_i}\}_i$ are then given by the sum of the individual payouts

$$F_I(t; \{t_{s_i}\}_i, \{\Delta_{s_i}\}_i) \equiv \sum_{i=1}^{N_s} f_I(t - t_{s_i}; r_c \Delta_{s_i} k_p(t_{s_i})),$$

where index i labels the shock number, and N_s denotes the total number of shocks.

A.1.2 Model calibration

We assume that, in the absence of shocks, the economy evolves along its *balanced growth path* (BGP), where output growth is constant and only driven by TFP growth (growth rate Λ),

$$g \equiv \frac{\dot{y}}{y} = \frac{\dot{A}}{A} + \alpha \frac{\dot{k}}{k} = \Lambda + \alpha g \quad \Leftrightarrow \quad \Lambda = (1 - \alpha)g, \quad (7)$$

where we have used in the second identity that if y growth constantly with rate g , k also growth constantly with the same rate². Since in the absence of shocks $F_I(t) = 0 \quad \forall t \in [0, T]$, where T denotes the length of the simulation, the dynamic equations for k and k_l decouple (cf. Eqs. (1)), it suffices to solve the equations of motions for the dynamic variables A and k along the BGP. The corresponding equation for k_l can then be derived from Eq. (1c). To this end, we insert the coordinate transformation

$$A(t) = e^{\Lambda t} \tilde{A}(t) \quad \& \quad k(t) = e^{gt} \tilde{k}(t),$$

into the dynamic equations for A and k yielding,

$$\dot{\tilde{A}}(t) = 0, \quad (8a)$$

$$\dot{\tilde{k}}(t) = s\tilde{y}(t) - (\delta + r_l + g)\tilde{k}(t), \quad (8b)$$

¹It is worthy to note, that according to Eq. (3) this is identical to expressing asset losses relative to the output in the year before the shock as done for the calibration of the model to empirical data in Sec. A.1.2

²This can be seen as follows: From the first identity in Eq. (7), it follows that the growth rate of the capital stock $\frac{\dot{k}}{k} = \frac{g-\Lambda}{\alpha}$ is constant when g is constant. From Eq. (2) it then follows that k and y have to grow with the same rate g .

where we have introduced the output in BGP coordinates $\tilde{y}(t) \equiv A^0 \tilde{k}^\alpha(t)$. Equating the right-hand-sides of Eqs. (8) to zero, yields the steady states for A and k in BGP coordinates

$$\tilde{A}^* = A^0, \quad \& \quad \tilde{k}^* = k^0 = \left(\frac{sA^0}{\delta + r_l + g} \right)^{\frac{1}{1-\alpha}}, \quad (9)$$

where $(\cdot)^*$ and k^0 denote the steady state values of variables and k^0 initial capital stock, respectively. This allows to write the BGP solution of Eqs. (1) as

$$A(t) = e^{\Lambda t} A^0, \quad k(t) = e^{gt} k^0, \quad k_l(t) = \frac{r_l}{g} [k(t) - k^0] = \frac{r_l}{g} k^0 [e^{gt} - 1]. \quad (10)$$

To calibrate the model to the US, we set initial per-capita annual output y^0 and output growth rate g to the per-capita growth domestic product (GDP) and the GDP growth rate of the US in 2015 according to the World Banks' and OECD's National Accounts database³, whereas capital depreciation rate δ , savings rate s , and capital share of income α are set to their standard values for developed economies⁴⁷. Using the Cobb-Douglas relation for the production function $y = Ak^\alpha$ and the steady state relation for k^0 (cf. Eq. (9)) then allows to express initial TFP and initial per-capita stock as $A^0 = y^0 \left(\frac{\delta + r_l + g}{s} \right)^\alpha$ and $k^0 = sy^0(\delta + r_l + g)^{-1}$, respectively.

Table 1 lists all exogenous parameters used in the simulations. It is worthy to note that our model results are very robust with regard to changes of the GDP growth rate g since we only consider changes of the perturbed economy relative to an unperturbed economy evolving along the BGP. Even large variations of $g \in [0.2\%, 4\%]$ result in changes of growth losses that are small compared to the climate uncertainties (cp. lines and shaded areas in supplementary Fig. S6)

Modelling a non-profit insurance scheme, we have to ensure that, averaged over many realisations, the insurance does neither make profit nor losses. However, deriving an exact analytical formula for the corresponding insurance premium r_l is challenging since – as output losses and growth losses – it would depend upon shock heterogeneity. Instead, we here motivate a simple heuristic formula neglecting this dependence and show that the resulting average insurance profits or losses are negligible compared to the cumulative payouts of the insurance. In the worst case, the total relative asset losses occur at the last time step of the simulation. Covering this loss would require an insurance capital stock of

³<https://data.worldbank.org/indicator/NY.GDP.PCAP.CD>

Quantity	Symbol	Value	Unit
Initial GDP per capita	y^0	51638.1	US\$
GDP growth rate	g	2.6%	year ⁻¹
Savings rate	s	0.2	year ⁻¹
Capital depreciation rate	δ	0.1	year ⁻¹
Capital share of income	α	0.7	
Time step length	Δt	$\frac{1}{52}$	year
Insurance payout parameter one	a	10^9	
Insurance payout parameter two	β	0.0741	
Insurance payout parameter three	τ_I	$1.31 \cdot 10^{-18}$	year
Empirical insurance premium coefficient	ε	$4.046 \cdot 10^{-4}$	
Simulation period	$\mathcal{T}$	35	year
Cumulative relative historical asset losses	$\Delta_{\mathcal{T}}$	3.24	%
Number of historical landfalling hurricanes	N_s	88	
Standard deviation of historical log-normal asset loss distribution	σ_0	0.10654	

Tbl. 1. Exogenous parameters used in the numerical simulations.

$k_l(\mathcal{T}) = r_c \Delta_{\mathcal{T}} k(\mathcal{T})$, where $\mathcal{T}$ denotes the length of the simulation. Inserting this relation in the BGP solution for k_l (cf. Eq. (10)) provides us with the following expression for the insurance premium

$$r_l \equiv \varepsilon \frac{gr_c}{1 - e^{-g\mathcal{T}}},$$

where we have added an empirically determined factor ε ensuring that average insurance profits (or losses) are negligible. (cf. supplementary Fig. S4 revealing that average profits or losses of the insurance are about five magnitudes smaller than the insured capital.

A.2 Gini index as measure for shock heterogeneity

We fit the relative asset losses of the $N_s = 88$ historical hurricanes with landfall included in the NatCatSERVICE database¹ (cf. Tbl. S1) with a log-normal distribution (supplementary Fig. S3) with standard deviation σ_0 . To change the heterogeneity of the loss events, we vary the standard deviation σ of the log-normal distribution from $\frac{\sigma_0}{100}$ to $4\sigma_0$. We use the Gini index $G \equiv \frac{L_e - L_l}{L_e} \in [0, 1]$ as measure for the shock heterogeneity, which is derived from the difference of the areas below the Lorenz-curves for a uniform distribution L_e and the given shock distribution L_l (cf. Fig. 2). Shock heterogeneity increases from small to large values of the Gini index. Noteworthy, the Gini index of the historical timeseries of hurricanes with landfall equals 0.829, whereas the median Gini index of the historical shock distribution – obtained by averaging over many synthetic realisations of asset loss time series (see Sec. A.3 for details) – equals 0.71.

A.3 Generation of synthetic time series of asset losses

In this section, we discuss the generation of synthetic time series of asset losses from their historical distribution as reported by the NatCatSERVICE¹ and TCE-DAT databases⁵¹. For the study period 1980–2014 of $\mathcal{T} = 35$ years, these databases list $N_s = 88$ hurricanes with landfall that have caused asset losses corresponding to at least 10^{-4} % of the GDP in the year of their landfall (see supplementary Tbl. S1). Over this period, relative asset losses accumulated to $\Delta_{\mathcal{T}} = 3.24\%$. We generate synthetic time series of asset losses of length $\mathcal{T}$ keeping N_s and $\Delta_{\mathcal{T}}$ at their historical values in three steps illustrated in supplementary Fig. S5. First, following ref.³¹, we assume that the number of hurricanes with landfall n_a

in each season a is Poisson distributed, $f_p(n_a) \equiv \frac{\lambda^a e^{-\lambda}}{n_a!}$. Further, we assume that the mean number of landfalls per season λ is constant over the study period $\mathcal{T}$. To ensure that each synthetic track contains exactly N_s shocks, the shock number for the last season of the track is set to the remainder of available shocks $N_s - \sum_{a=1}^{\mathcal{T}-1} n_a$. To avoid that the last season always receives the remainder of available shocks, seasons are shuffled afterwards. Second, we assume that for each day of the season the likelihood of a hurricane making landfall is the same, but exclude the possibility that two hurricanes make landfall at the same day. Third, following ref.³² (cf. Fig. S3 in SI), we assume that relative asset losses Δ_s are log-normally distributed, $f_{LN}(\Delta_s) \equiv \frac{1}{s\Delta_s\sqrt{2\pi}} \exp\left[-\frac{(\ln(\Delta_s)-m)^2}{2s^2}\right]$, where we have introduced the parameters $s \equiv \left(\ln\left(\frac{\sigma^2}{\frac{\Delta_{\mathcal{T}}}{N_s} + 1}\right)\right)^{\frac{1}{2}}$, $m \equiv \ln\left(\frac{\Delta_{\mathcal{T}}}{N_s}\right) - \frac{s^2}{2}$, and the standard deviation σ of the log-normal distribution. Similarly, to step one the size of the last shock of each realisation is set to the difference between $\Delta_{\mathcal{T}}$ and cumulative relative asset losses before the last shock in order to ensure that total cumulative relative asset losses equal $\Delta_{\mathcal{T}}$; then shock sizes are reshuffled.

A.4 Storm surge- and wind field-based climate change projections of asset losses

Storm surge-based projections of asset losses. Grinsted et al.⁶ estimated the relative increase in the return frequency of hurricanes with landfall in dependence of the severity of their storm surge (measured by the surge index⁵²) per degree of global mean temperature (GMT) warming relative to the reference period 1980–2000. We employ these findings to project asset losses for a $+2^\circ\text{C}$ increase of GMT above its pre-industrial level⁴. To this end, we first map the surge indices $\{f_{s_i}\}$ of the $N_s = 88$ historical hurricanes that made landfall in the US between 1980–2014 to the corresponding relative asset losses $\{\Delta_{s_i}^h\}$ reported in the NatCatSERVICE database¹ (supplementary Tbl. S1). Next, we determine the statistical correlation between historical asset losses and surge indices, yielding the damage function $f(s)$ (supplementary Fig. S7). As discussed in the main text, we assume that the average number of hurricanes with landfall will not change compared to the historical study period.

⁴Note that one degree of global warming compared to 1980–2000 corresponds to 1.5°C of warming compared to the pre-industrial level⁵³

In consequence, we interpret the increases in return frequency reported by Grinsted et al. as increases solely in storm surge intensity, and not as an increase of the average number of hurricanes making landfall (in each season). This allows us to map the set of historical surge indices $\{f_{s_i}\}$ to a set of estimated surge indices in a $+2^\circ\text{C}$ world $\{f_{s_i}^{cc}\}$. We then assume that each future relative asset loss $\Delta_{s_i}^{cc}$ can be written in terms of the corresponding historical asset loss. This allows to express future relative asset losses in terms of the historical relative asset losses as well as future and historical storm surge indices,

$$\Delta_{s_i}^{cc} \equiv \Delta_{s_i} + f(f_i^{cc}) - f(f_i^h). \quad (11)$$

Note that with this relationship historical asset losses are reproduced for $f_i^{cc} = f_i$. Employing Eq. (11), we project relative asset losses $\Delta_{\mathcal{T}}$ accumulated over $\mathcal{T} = 35$ years to increase substantially from their historical value of 3.24% to 7.25%. We then generate synthetic realisations of future asset loss time series by distributing the projected $N_s = 88$ relative asset losses over the simulation time of $\mathcal{T} = 35$ years as described in Sec. A.3.

Wind field-based projections of asset losses. Knutsen et al.⁷ analysed an ensemble of downscaled global climate models participating in the 5th phase of the Coupled Model Intercomparison Project (CMIP5). Based on the wind fields of the storms they estimated a median decrease of 22% in the overall number of all hurricanes but a median increase of the most intense Category 4 and 5 storms by 45% for an increase of GMT by $+2^\circ\text{C}$ above its pre-industrial level under the Representative Concentration Pathway (RCP) 4.5. To estimate the associated changes in asset losses, we first divide the $N_s = 88$ historical hurricanes that made landfall in the US in the period 1980–2014 into moderate (Category 0-3, 66 storms) and intense (Category 4-5, 22 storms) storms based on the IBTRaCS database⁵⁴. Applying then the estimates of Knutsen et al., we project that in a $+2^\circ\text{C}$ degree world the number of all hurricanes and the number of moderate hurricanes decrease to 69 and 37, respectively, whereas the number of intense hurricanes increase to 32. This would lead to a minor change of relative cumulative asset losses $\Delta_{\mathcal{T}}$ from their historical value of 3.24% to 3.75%. Synthetic time series of future asset losses are finally generated as described for the surge-based estimate.

Code availability

The implementation of the *InGroCIIM* model is available as open source on <https://github.com/kuhla/InGroCIIm> with identifier [10.5281/zenodo.5017904](https://doi.org/10.5281/zenodo.5017904).

Tbl. S1. Historical hurricanes that made landfall in the US between 1980 and 2014.

1st through 4th columns list names and years of landfall of the storms as reported by IB-TRaCS database⁵⁴, storm severity (category 4-5 hurricanes according to Saffir-Simpsons scale⁸), and storm surge index according to ref.⁵², respectively. The 5th column reports categorized asset losses based on reported asset losses by Munich Re's NatCatSERVICE database¹: small ($> 10^{-5}\%$), moderate ($> 10^{-4}\%$), strong ($> 10^{-3}\%$), severe ($> 10^{-2}\%$). The asset losses are measured relative to the growth domestic product of the US (according to World Banks' and OECD's National Accounts database⁵) in the year of landfall.

Name	Year	Cat. 4-5 hurricane	Surge index	Asset losses category
Alberto	1994		9.2	strong

Fig. S1. Recovery dynamics of production capacity in dependence of shock heterogeneity for 1% reconstruction investment limit. Same as Fig. 2 but for a 1% reconstruction investment cap.

Fig. S2. Insurance payout dynamics. Cumulative (brown) and monthly (violet) insurance payouts in the aftermath of an individual shock to the physical capital stock. The sigmoidal function for the cumulative payouts is calibrated such that 60% (90%) of the insured values are reimbursed within one (three) year(s) according to insurance data of the Reinsurance Association of America²⁸. The monthly payouts are then obtained by deriving this function with respect to time.

Fig. S3. Distribution of the historical asset losses of hurricanes that made landfall in the US in the period 1980–2014.

Black dots depict the asset losses as reported by the NatCatSERVICE database¹ in the period 1980–2014 relative to the US growth domestic product of the years in which the hurricanes made landfall. The red line depicts a fit with a log-normal cumulative density function.

Fig. S4. Insurance is non-profit. Median insurance capital stock in terms of the insured potential capital stock after $\mathcal{T} = 35$ years. Same scenarios and colour code as in Fig. 1.

Fig. S5. Sketch of construction of synthetic asset loss time series caused by hurricanes with landfall. Synthetic time series of asset losses are generated in three steps: First, the number of hurricane shocks in each US hurricane season (June–November) is drawn from a Poisson distribution f_P . Second, the times of landfalls are determined assuming the same probability of landfall within each season, excluding the possibility of two landfalls on the same day. Third, the relative asset loss of each landfall is drawn from the log-normal distribution of Fig. S3.

Fig. S6. Robustness of relative growth losses with regard to choice of baseline growth rate. Dependence of relative annual growth losses upon the growth rate of corresponding unperturbed baseline scenario for an insurance coverage of 50% without reconstruction investment limit (blue) as well as for reconstruction investment caps of 0.2% (red) and 1% (green) of weekly output. Lines indicate median growth rate reductions and shaded areas the corresponding 16.7–88.3 percentile confidence intervals.

Fig. S7. Dependence of asset losses on surge index. Log-log plot of asset losses (grey dots) of the 88 historical hurricane that made landfall in the US between 1980 and 2014 according to NatCatSERVICE database¹ relative to the growth domestic output the year of landfall (according to the World Banks' and OECD's National Accounts database^a) as function of their surge index⁵². The red line denotes a non-linear fit of the data (damage function $f(f)$). The Pearson's chi-squared criteria for the goodness-of-fit is $\chi^2 = 0.59$.
