Abstract

This empirical study examines the endogenous relationship between carbon emission (CO₂), financial development, renewable energy, globalization, and institutional quality in 64 belt and road initiative countries (BRI) using a two-step system generalized method of moments (GMM) approach with panel data over the period 2003 to 2018. Furthermore, this study used (Dumitrescu & Hurlin, 2012) causality test to estimate the variables' causal relationship. The results indicate that financial development significantly increases CO₂ emissions and causes environmental degradation in BRI countries. However, renewable energy and globalization mitigate CO₂ emission and improve the quality of the environment. Institutional quality was found to be positive in correlation with CO₂ emission and indicates bad governance, corruption, weak bureaucracy, and improper implementation of environmental laws cause environmental degradation. Further, the study also reports a bidirectional relationship of financial development, renewable energy, and institutional quality with CO₂ emission and a unidirectional causality running from globalization to CO₂ emission in BRI countries. This study offers insight to policymakers to restructure the financial system, energy consumption pattern, and global integration and to improve institutions' quality for a sustainable environment and the economy at the national and regional levels.

Keywords: Financial development, Carbon emission, Renewable energy, Globalization, Institutional quality

1. Introduction

Global warming and climate change are the most serious global threats the world is facing today. Globalization and economic growth are the essential factors that raise carbon emissions (CO₂) and greenhouse gases (GHGs). For the past few decades, global warming and climate change have been subjects of discussion and concern among research scholars, experts, and governments. As an estimation, carbon emission (CO₂) contributes 60% of greenhouse gases, which are the cause of global warming and climate change (Eren et al., 2019; Ozturk & Acaravci, 2010; Wang & Chen, 2014). Moreover, the extracting natural resources (e.g., natural oil, gas and coal) without any compensation directly impact on environmental quality. According to an estimate, in the past 130 years, there has been approximately a 45% increase in carbon emission (Carbon Footprint, 2018, Adger & Coauthors, 2018).

Thus, scholars, governments, and experts have reached the consensus that the Paris global climate conference objectives (COP21) can only be attained by minimizing the carbon and greenhouse gas emissions (Bhattacharya et al., 2017; Pérez et al., 2017). However, Cardenas et al. (2016) believe that global efforts against global warming and climate change are insufficient. Hence, it is crucial to have pro-environmental regulations and policies. However, scholars, experts, and economists' biggest challenge is to make a combined plan (by formulating new policies, and environmental laws by keeping the same pace of economic growth) against environmental degradation (Charfeddine et al., 2018; Kahia et al., 2017).

In practical terms, while making an environmental strategy that can reduce carbon emission, it is essential to consider several policy options. Particularly, from the macro-economic, ecological, energy, governance, and global perspectives, the following propositions are of particular interest: (1) development of the financial sector (FD), (2) switching toward renewable energy (REC), (3) promoting globalization (GB), (4) improving institutional quality (IQ), and (5) interaction between financial development and renewable energy, globalization, institutional quality, GDP and carbon emissions.

The first proposition entails financial development, which is a source of financing for various projects and also interconnects with economic growth (GDP) and environmental quality (Khan et al., 2017). The financial sector lends to private creditors through institutions and economic activities takes place (Khan, 2001). However, it is still questionable whether financial development improves the quality of the environment or not as past studies have not arrived at any consensus Khan et al. (2017), Saud et al. (2020), Wang et al. (2020), and Zhang (2011) reported financial development as the cause of environmental degradation. However, Saud et al., (2018) and Shahbaz et al., (2013; 2018) argue that financial development improves the environment's quality.

The second proposition is based on promoting renewable energy consumption (REC) as it helps cut down carbon emissions. Chang et al. (2020) state that fossil fuel energy is the primary source of carbon emission and environmental degradation. As per IEA and OEC (2018), renewable energy consumption will increase by 60% by 2040. Sadorsky (2011) claims that for a clean and green environment, it is important to have 50% to 80% of the energy being used as renewable. Earlier studies (Balsalobre et al., 2018; Z. Khan et al., 2020) have argued that the global industrial structure is switching toward sustainable and green economics which will reduce carbon emission. Bao and Xu (2019), Charfeddine and Kahia (2019), Hao et al., (2021), Rahman and Velayutham (2020), and Uzar (2020) indicate that switching to renewable energy would lead to a sustainable environment.

Globalization is another important factor from the social, economic, and political aspects of life as it connects economies through financial development and foreign direct investment GDP and causes environmental degradation in the form of carbon and sulfur emission (Mishkin, 2009; Shahbaz et al., 2015). Globalization accelerates financial activities as it increases the demand for goods and services (Gökmenoğlu & Taspinar, 2016). Consequently, economic activities increase which increases energy consumption, leading to environmental degradation (Ozatac et al., 2017). Past studies have mixed findings regarding globalization and its impact on the environment. One school of thought argues that globalization improves the quality of the environment (Jorgenson & Givens, 2014; Li et al., 2015; Shahbaz et al., 2016, 2017, 2019; Zafar et al., 2019; Zaidi et al., 2019). Conversely, another school of thought (Doytch & Uctum, 2016; Saud et al., 2020; Shahbaz et al., 2015) indicates that globalization causes carbon emission.

Another critical proposition is institutional quality, which entails corruption, good governance, the implication of law, and quality of bureaucracy. It is an ignored factor in the context of environmental quality and climate change (Godil et al., 2020; Hunjra et al., 2020; Ibrahim & Law, 2016; Z. Wang et al., 2018). Institutional quality is vital to adopting renewable energy, green investment, and global trade through various factors, mainly the focus on the cost of adaptation and willingness to pay or policy choice (Cole, 2007; Dutt, 2009; Tamazian & Bhaskara, 2010). Institutional quality improves environmental quality when government institutions effectively implement environmental law and regulations (Lau et al., 2014). Unlike previous studies, we attempt to focus on how explanatory variables and carbon emission depend on belt and road initiative countries (BRI) institutional differences. Does this difference among the BRI countries have implications for green investment, renewable energy, and globalization? Finally, does institutional quality help in reducing carbon emission in BRI countries?

This research study focuses on BRI, a group of new emerging countries. This “silk and road economic belt” comprises more than 65 countries (48 more countries showed interest), launched in December 2014 with a starting investment of 1.4 trillion to 6 trillion US dollars. BRI countries consist of 4.4 billion people covering 62.3% of the world population and represent 34% of world GDP (NDRC, FM and MC, 2015). BRI co-operation countries cover the western Pacific’s beltline to the Baltic Sea, which has enormous economic significance. This project focuses on facilitating free trade for BRI countries by giving physical and digital access to global markets through global integration (globalization), financial integration, infrastructure, trade openness, and efficient use of resources, with policymaking and coordination within the region (Institutional quality) (Chin, 2017; Chin et al., 2015). All these factors create additional demand for energy, which directly impacts the environment. Hence, this project’s core objectives are to provide healthier financial and global integration, switching toward green energy, and better governance to improve the quality of the environment (HKTDC, 2017).

For theoretical proposition, global warming and environmental quality have become a core issue for the future of BRI economies. Therefore, it is essential to address core factors like the extent to which financial development, energy consumption, globalization, and institutional quality influences carbon footprint. This study's implication will unfold the vision and objectives useful for policymakers and relevant authorities. Further, it will advise stakeholders regarding the sort of policy necessary to cut down carbon emission through expected financial development, energy consumption, and globalization.

Considering the above arguments related to environmental adversity, this study conducts an in-depth investigation particularly in the aspects of economy, energy, regional connectivity, governance, and ecology as follows: first, this empirical research fills the gap in the literature by incorporating financial development (FD), renewable energy (REC), globalization (GB), and institutional quality (IQ) as primary explanatory variables for environmental quality (CO₂) in a single multivariate framework. Besides, we also used GDP and socioeconomic

factors as control variables. As per our best knowledge, this will be the first study incorporating institutional quality as an explanatory variable with financial development, renewable energy, and globalization with respect to carbon emission in the same framework. Second, previous studies have had mixed results regarding explanatory variables on environmental quality (CO₂). To address these issues, we will provide a comprehensive guideline for policymakers, institutions, and other stakeholders to formulate new policies, techniques, and laws to cut down carbon emission. Third, we used a dynamic system, “Generalized Method of Moment” (GMM), a panel technique for reliable findings. Unlike other econometric techniques, it addresses heterogeneity and endogeneity by using Hansen/Sargan test and providing additional information about autocorrelation AR (1) and AR (2). Further, we also used panel Granger causality to check the causal relationship between the variables. Fourth, our study sample comprises 64 BRI countries with a sample of 16 years starting from 2003 to 2018.

The road map of the paper is as follows: the second section provides a literature review of past studies, third presents data sources, fourth presents empirical results, and fifth provides discussion and conclusion.

2. Literature Review

This section of the article is based on past literature, which indicates the nexus of financial development, renewable energy, globalization, institution quality, and carbon emission.

2.1 Financial Development and Carbon Emission

Since the day the EKC concept was proposed by Grossman and Krueger (1995), several studies have examined the nexus between FD and CO₂ emission. Financial institutions finance investors and the household sector so economic activities take place (Khan, 2001). However, there is no consensus among researchers. Khan et al. (2017) investigated the nexus between financial development, energy consumption, trade, urbanization, and carbon emission in the case of 34 upper middle-income countries of the world. Using panel vector error correction (PVAR) and fully modified ordinary least square (FMOLS) model, results confirm that financial development causes environmental degradation in European and Asian countries. Similarly, Saud et al. (2020) analyzed the impact of financial development and globalization on ecological footprint (environment) in BRI countries. The study used a panel ARDL model with a sample period from 1990 to 2014. Results indicate that financial development and globalization cause environmental degradation. The relationship between financial development and carbon emission was also studied (Charfeddine & Kahia, 2019; Wang et al., 2020; Zhang, 2011; Zioło et al., 2020) and it was supported that financial development causes carbon emission.

Shahbaz et al. (2013) studied the relationship of financial development, energy consumption trade openness and carbon emission in Indonesia. Using the ARDL and VECM Granger causality test, findings confirm that financial development and trade openness improve the environment's quality; however, GDP and energy consumption increased carbon emission. Saud et al. (2018) and Shahbaz et al. (2018) also investigated the relationship between financial development and carbon emission. Their findings indicate that financial development improves the quality of the environment by mitigating the carbon emission.

2.2 Renewable Energy Consumption and Carbon Emission

One of the critical factors for a green and clean environment is switching to renewable energy. Several previous studies have examined the relationship between renewable energy and its impact on environmental quality. To extend the argument, Bhattacharya et al. (2017) analyzed the association between renewable energy and institutional quality with respect to carbon emission in 84 countries of the world. They used the system GMM and FMOLS model; results indicate that renewable energy and carbon emission improve the environment's quality as it reduces carbon emission.

Similarly, Balsalobre et al. (2018) conducted a study in five European countries to investigate the impact of renewable energy, trade openness, GDP, and natural resources on carbon emission. Results indicate that renewable natural resources improve environmental quality; however, GDP and trade openness cause carbon emissions. Hao et al. (2021) and Khan et al. (2020) investigated the relationship of renewable sources with environmental quality in G7 countries. They showed that green energy improves the quality of the environment. Moreover, Bao and Xu (2019),

Charfeddine and Kahia (2019), Rahman and Velayutham (2020), and Uzar (2020) also reported the same trend for renewable energy and carbon emission.

2.3 Globalization and Carbon Emission

Another vital variable that directly impacts the quality of the environment is globalization. Though past studies provide mixed evidence related to its effects on environmental quality. To extend the argument, a school of thought claims that globalization improves the quality of the environment. Sheraz et al. (2021) revealed that globalization helps developing countries import new technology for the efficient use of energy. Zaidi et al. (2019) investigated the linkage of globalization and financial development with carbon emission in Asia-Pacific economic co-operation countries. Using the data from 1990 to 2016, results demonstrate that globalization and financial development cut down the carbon emission. Furthermore, Jorgenson and Givens (2014) and Zafar et al. (2019) also reported that globalization improves the environment's quality. Shahbaz et al. (2017) used the ARDL test to confirm that globalization enhances the quality of the environment. Shahbaz et al. (2016; 2019) investigated 87 high-, middle- and low-income countries and selected African countries. Their findings confirm that globalization improves the quality of the environment.

Conversely, another school of thought supports the argument that globalization causes carbon emissions. Shahbaz et al. (2015) conducted a study in India to investigate the linkage of globalization, financial development, GDP, and energy consumption with carbon emission. Results of the study showed that globalization, financial development GDP, and energy consumption increased carbon emission. Similarly, Saud et al. (2020) investigated the impact of globalization, financial development, GDP, and energy consumption on carbon emission in BRI countries. Findings also confirm that globalization causes environmental degradation. Doytch and Uctum's (2016) findings also indicate that globalization increases carbon emission.

2.4 Institutional Quality and Carbon Emission

Institutional quality is the most ignored factor in the context of environmental quality. Institutional quality plays a significant role in reducing carbon emission. Bhattacharya et al. (2017) analyzed 85 countries and reported that institutional quality has a negative and positive correlation with carbon emission and GDP. It indicates better governance and implication of law and policies improved the environmental quality and increased the GDP. Similarly, Ibrahim and Law (2016) and Wang et al. (2018) also confirmed that better institutional quality positively moderates the GDP development and carbon emission. Further, institutional reference improves the environment's quality but countries with low institutional quality led to environmental degradation.

Conversely, the findings of Godil et al. (2020) indicate that institutional quality and GDP increase carbon emission but financial development, information, and communication technology reduce carbon emissions in Pakistan's case. Similarly, Hunjra et al. (2020) analyzed the nexus of financial development and carbon emission with a moderating role of institutional quality in five south Asian countries. Results showed that institutional quality negatively moderates financial development and carbon emission.

Table.1 Summery of the Nexus Between Financial Development, Renewable Energy, Globalization, Institutional Quality, GDP and Carbon Emission

Name of Author/Year	Sample Size/Region	Modeling Technique	Results
Charfeddine & Kahia, (2019)	Middle east and North Africa (1980–2015)	PVAR	FD is positive but insignificant, but REC improves environmental quality. However, GDP causes carbon emission.
Khan et al., (2017)	34 countries of the world (2001–2014)	PVAR/FMOLS	FD, FDI, and urbanization cause carbon emission, however, REC improve the quality of the environment.

Saud et al., (2020)	BRI countries (1990–2014)	PARDL and Granger causality	FD and GB cause carbon emission and have a feedback relationship with carbon emission.
Wang et al., (2020)	N-11 countries (1990–2017)	Common correlated effect mean group and Augmented mean group	FD and GDP increase carbon pollution; however, REC and human and energy innovation improve the environment's quality.
Zhang (2011)	China (1986–2009)	VAR/Granger causality	FD and GDP stigmatically cause environmental degradation.
Ziolo et al., (2020)	European countries (2008–2017)	Eigen analysis	FD causes environmental degradation
Shahbaz et al., (2013)	Indonesia (1975–2011)	ARDL/VECM Granger causality	FD and trade openness improve the quality of the environment, but GDP and energy consumption cause carbon emission
Shahbaz et al., (2018)	France (1955–2016)	Bootstrapping ARDL	FD improves the quality of the environment but foreign direct investment and energy cause carbon emission.
Saud et al. (2018)	BRI (1980–2016)	Dumitrescu and Hurlin model (DSUR)	FD and foreign direct investment improve the quality of the environment.
Bhattacharya et al., (2017)	85 countries (1991–2012)	System GMM/FMOLS	REC and IQ improve the quality of the environment
Balsalobre et al., (2018)	5 European countries (1985–2016)	PLS	REC and natural resource improve environmental quality, but GDP and trade openness cause carbon emission.
Khan et al., (2020)	G7 countries (1990–2017)	CCEMG/AMG	REC and technology innovation improve the quality of the environment, but GDP and imports cause carbon emission.
Hao et al., (2021)	G7 countries (1991–2017)	CSARDL	REC, human capital, and taxes improve the quality of the environment, but GDP causes carbon emission.
Zaidi et al., (2019)	APEC countries (1990–2016)	CUP-BC/CUP-FM	GB and FD improve the quality of the environment.
Shahbaz et al., (2017)	China (1970–2012)	ARDL /VECM Granger causality	GB improve the quality of the environment
Shahbaz et al., (2019)	87 countries (1970–2012)	Cross-correlation approach	GB cuts down the carbon emission
Shahbaz et al., (2016)	African countries (1971–2012)	PARDL	GB improves the quality of the environment

Shahbaz et al., (2015)	India (1970-2012)	PARDL	GB, FD, GDP, and energy consumption increase environmental degradation.
Ibrahim & Law, (2016)	40 African countries (2000-2010)	Dynamic GMM	IQ improves the quality of the environment but trade impacts carbon emission demand of IQ.
Z. Wang et al., (2018)	BRICS countries (1996-2015)	Piratical least square regression	Corruption weakens the relationship between carbon emission and GDP
Godil et al., (2020)	Pakistan (1995-2018)	Quantile ARDL	IQ and GDP cause carbon emission, but FD and information technology improve the quality of the environment.
Hunjra et al., (2020)	5 south Asian countries (1984-2018)	GLS	IQ negatively moderates FD and carbon emission.

177

178 3. Model Description, Data and Estimations

179 3.1 Data Collection and Theoretical Modeling

180 This study examined the effects of financial development, renewable energy, globalization, and institutional
181 quality on carbon emission for 64 belt and road initiative countries (BRI) for 2003 to 2018 as per data availability.
182 Our study sample comprises upper middle, middle- or lower-income countries of East Asia, South Asia, Central Asia,
183 Middle East, North Africa, South Africa, and Europe (details in Appendix A Table 8). The sample of the study is
184 based on secondary data obtained from “world development indicators” (WDI) and the “international country risk
185 guide” (ICRG) database provided in Appendix-B, Table 9.

186 The variables selected for the analysis are as follows: (1) Carbon emissions are measured in per capita metric
187 tons; (2) Financial development index comprises sub-indices of financial market index and financial institutional
188 index; (3) Renewable energy is the aggregate of wind, hydro, solar, geothermal, marine, waste and gaseous biofuel
189 derived energy; (4) KOF proposes the globalization index and comprises sub-indices of economic, social, and political
190 global indices; (5) The institutional quantity index comprises six governance indicators (the rule of law, control of
191 corruption, government effectiveness, voice and accountability, regulatory quality, and political stability and absence
192 of terrorism); (6) GDP is the measure of growth which is constant 2010 US dollars; (7) Socioeconomic index
193 comprises sub-indices of poverty index, consumer price index and unemployment. All the determents are transformed
194 into natural logarithm form (except financial development index globalization index, and intuitional quality index).

195 The study’s empirical framework is based on carbon emission (CO₂) as a dependent variable, while financial
196 development, renewable energy, globalization, and institutional quality are explanatory variables. We also used gross
197 domestic product (GDP) and socioeconomic factors (SEC) as control variables. The framework or functional form of
198 our model is specified as follows:

$$199 \text{Co}_2 = f(\text{FD, REC, GB, IQ, GDP, SEC}) \quad \text{Eq. (A. 1)}$$

200 where FD, REC, GB, IQ, GDP, and SEC represent financial development, renewable energy consumption,
201 globalization, institutional quality, gross domestic product, and socio-economic conditions.

202 Based on previous literature, FD is the primary source of funding for economic activities. Financial institutions
203 lend to the private firms and household sectors at a low cost of borrowing. However, economic activities increase the
204 energy demand which causes carbon emission too. Like Khan et al. (2017a), Saud et al. (2020), Wang et al. (2020),
205 and Zhang (2011), we also expect a positive relation between FD and carbon emission. Several past studies (Bao &
206 Xu, 2019; Charfeddine & Kahia, 2019; Rahman & Velayutham, 2020; Uzar, 2020) have argued that RE improves the

environmental quality by abating the carbon mission so we also assume a negative impact of RE on carbon emission. Another important determinant is GB which has a significant effect on environmental quality. GB helps make investment in green projects and import of the green technology from developed countries that mitigate the energy impact on the environment. Based on some studies' findings (Zaidi et al., 2019, Jorgenson & Givens, 2014; Zafar et al., 2019, Shahbaz et al., 2016, 2019), we expect a negative impact of GB on carbon emission in BRI countries. Finally, IQ, which comprises six sub-indices, is vital in improving environmental quality as strong institution and better governance help implement the environment-related laws and regulations. Based on the previous findings (Godil et al., 2020; Hunjra et al., 2020; Ibrahim & Law, 2016; Wang et al., 2018) we expect a negative impact of IQ on carbon emission in BRI countries.

3.2 Empirical Estimation Techniques

3.3.1 Diagnostics Tests (IPS & CIPS unit root, CD test)

This study employed the most advanced econometric approach to test cross-sectional dependence (CD) between the variables as conventional econometric approaches cannot address this issue. Therefore, we adopted Pesaran's (2004) cross-sectional dependence test which is crucial before a unit root test. We used following equations for cross-sectional dependence and Lagrange multiplier (LM):

$$CD = \sqrt{\frac{2T}{N(N-1)}} \left(\sum_{i=0}^{N-1} \sum_{j=i+1}^N \rho_{ij} \right) \quad \text{Eq. (A. 2)}$$

$$y_{it} = \alpha_{it} + \beta_i x_{it} + \mu_{it} \quad \text{Eq. (A. 3)}$$

Further, to confirm the stationarity of the variables, we employed second generation IPS (i.e. CADF) and CIPS (i.e. CIPS) unit root test proposed by Pesaran (2007). The unit root test helps confirm the integration order, whether the variable is stationary at level $i(0)$ or first difference $i(1)$. The following equations are used to estimate CADF and CIPS unit root test:

$$y_{it} = \alpha_{it} + \beta_i x_{it-1} \rho_i T + \sum_{j=0}^n \theta_{it} \Delta x_{i,t-j} + \mu_{it} \quad \text{Eq. (A. 4)}$$

$$CIPS = \frac{1}{N} \sum_{i=1}^N CADFi \quad \text{Eq. (A. 5)}$$

3.4.2 Pairwise Dumitrescu and Hurlin Causality test

After confirmation of CD, this study employed the causality test proposed by Dumitrescu and Hurlin (2012) based on the individual Wald statistic of Granger (1969) test. The empirical representation of the test is as follows:

$$y_{it} = \alpha_i + \sum_{j=1}^J \lambda_j^i y_{i(t-j)} + \sum_{j=1}^J \beta_j^i x_{i(t-j)} + \mu_{it} \quad \text{Eq. (A. 6)}$$

where y and x indicate the numbers of observations and λ and β_{ji} are the coefficients of regression and autoregressive parameters. The null hypothesis demonstrates no causal association among the variables and shows causal relationship between the variables.

3.4.3 Two-Step System GMM

This study's primary objective is to examine the impact of exoplanetary variables (FD, REC, GB, IQ) on CO₂ from BRI countries. However, due to the panel nature data, this study employed panel estimation techniques. The traditional panel models (Pooled OLS, random and fixed-effect panel) are not suitable due to country-specific effects, endogeneity of independent variables, and lagged dependent variables. Besides, error terms are not auto-correlated; therefore, traditional techniques do not efficiently estimate the results (Beggs & Nerlove, 1988). To address the aforementioned issues, Arellano and Bond (1991) proposed a panel estimation technique known as the generalized method of moments (GMM). In contrast with other panel estimation techniques, GMM addresses the issues of endogeneity, error of measurement, omitted variables, and autocorrelation issues. For instance, by taking the first difference, it can solve country-specific effects or time-invariant variable.

Moreover, to address the issues of correlation between lagged dependent variables and disturbance terms after the first difference, Arellano and Bond (1991) used instrumental variables (differenced lagged dependent variables and endogenous variables instrumented with their lags at levels; however, lagged two or more exogenous variables can serve their own instruments). GMM is further categorized into system GMM and difference GMM based on different weight matrixes. Each of them can be further divided into one and two-step GMM. However, system GMM is a better estimator technique than difference GMM, and two-step GMM better addresses the issues of heteroscedasticity and autocorrelation than one-step GMM (Arellano & Bover, 1995; Blundell & Bond, 1998; Arellano & Bond, 1991).

One of the basic criteria for system GMM is that the number of cross-sections (N) should be greater than period (T), which was met by the sample of this study, where T=16 and N=64 (N>T). Therefore, to achieve this study's objectives, we adopted dynamic panel model (two-step system GMM) for the estimation. Unlike static panel estimation technique, the dynamic panel model added lag term of the explained variable as the dependent variable. This will show the dynamic process of CO₂ emission close to reality. Besides, the addition of a lag term improves the regression outcomes' authenticity by addressing the impact of uncontrollable determinants.

Like past studies conducted by Adeleye & Eboagu (2019), Arminen (2018), Arminen and Menegaki (2019) and Ullah et al. (2021). The structural equations of simultaneous equations model can be as follows:

$$Y_{it} = X_{it}\beta + \delta y_{i,t-1} + c_i + \varepsilon_{it} \quad \text{Eq. (A. 7)}$$

$$\Delta y_{it} = (\Delta X_{i,t})\beta + \delta(\Delta y_{i,t-1}) + \Delta \varepsilon_{it} \quad \text{Eq. (A. 8)}$$

where the subscripts "t" and "i" indicate time and countries, such as t= 1, . . . , T, (16 years), i = 1, . . . , N (64 countries). Further, it is considered that the error term is the combination of idiosyncratic shocks ε_{it} and fixed individual effects c_i with the following characteristics: $E[c_i] = E[\varepsilon_{it}] = E[c_i\varepsilon_{it}] = 0$. Moreover, in Equation 7, the individual effect c_i is eliminated, where Δ represent first difference.

The linear form of static and dynamic model is as follows:

$$Co2_{i,t} = \beta_0 + \beta_1(FD)_{i,t} + \beta_2(REC)_{i,t} + \beta_3(GB)_{i,t} + \beta_4(IQ)_{i,t} + \beta_5(GDP)_{i,t} + \beta_6(SEC)_{i,t} + \varphi_t + \mu_{i,t} \quad \text{Eq. (A. 9)}$$

$$Co2_{i,t} = \alpha_i + \lambda(Co2)_{i,t-1} + \beta_1(FD)_{i,t} + \beta_2(REC)_{i,t} + \beta_3(GB)_{i,t} + \beta_4(IQ)_{i,t} + \beta_5(GDP)_{i,t} + \beta_6(SEC)_{i,t} + \varphi_t + \mu_{i,t} \quad \text{Eq. (A. 10)}$$

where i and t denote country specific values and time period, and CO₂, FD, REC, GB, IQ GDP, and SEC represent carbon emission, financial development, renewable energy consumption, globalization, institutional quality, gross domestic product, and socioeconomic conditions, respectively. Here, to account for temporal dependence on CO₂, we used lagged dependent variable, which presents the gradual changes in technology and production structure. Further, α_i indicates country-specific effect, λ , β_1 , β_2 , β_3 , β_4 , β_5 , β_6 represents the coefficients of cross-ponding explanatory variables, φ_t indicates the year dummies as it controls the common shocks (like global financial crises during 2007-2009); $\mu_{i,t}$ reports the error term.

Furthermore, to conduct the estimation, we used Stata-15 software and "Xtabond2" command. Roodman (2009) in his study provided more explanation about this command. We adopted the Hansen test over Sargan test as it is more robust concerning autocorrelation and heteroscedasticity (Roodman, 2009). Further, the Hansen test addresses the instrument's reliability and controls overidentifying restrictions. To confirm the estimator's consistency, a serial correlation test is used as it is based on first and second-order autocorrelation estimators.

4. Estimation Results and Discussion

Fig. 1 which represent the impact of FD and REC on CO₂ emission, suggest that the path of emission of CO₂ in BRI countries is influenced by the path of FD and REC. Fig.1 indicates an upward trend of FD increasing carbon emission; however, the downward trend of REC suggests it mitigates carbon emission.

Fig.1: CO₂, REC, FD represent carbon emission, renewable energy consumption and financial development.
Source: Authors Estimations Origin-Pro 2018

Similarly, the trend in Fig. 2 suggests the upward movement of IQ because of CO₂ emission. However, globalization shows a downward trend which suggests the mitigation of CO₂ emission in BRI countries.

Fig.2. CO₂, GB, and IQ represent carbon emission, globalization, and financial institutional quality.
Source: Authors Estimations Origin-Pro 2018

Table 2 presents the descriptive summary of the variables which indicates that the results of all variables of the study for mean, median, standard deviation, minimum, maximum, skewness, and Kurtosis are normalized. Moreover, the normal distribution probability trend of the curves for all the determinants are reported in Appendix C.

Variables	Obs	Mean	Median	Std. Dev.	Min	Max	Skewness	Kurtosis
Co2	1024	1.01	1.25	1.46	3.6	-2.9	-0.66	2.1
FD	1024	0.32	0.31	0.17	0.7	0.07	0.44	2.2
REC	1024	0.60	1.18	2.71	7.50	-6.90	-0.52	2.1
GB	1024	64.5	65.2	12.5	85.1	33.4	-0.44	2.6
IQ	1024	0.07	-0.10	1.01	3.4	-1.75	0.72	2.7

Mean VIF								1.597

Note: FD, REC, GB, IQ, GDP, and SEC represent financial development, renewable energy consumption, globalization, institutional quality, gross domestic product, and socio-economic conditions, respectively.

Note: Standard errors in parentheses at 1%, 5%, and 10% levels are *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$, respectively. VIF denote variance inflation factor.

Table 3 presents the results of pairwise correlation indicating the degree of relationship. All the independent variables have positive and significant relationship with CO₂ emission. The basic function of the correlation matrix is to detect issues of multicollinearity. Usually, it is assumed that if the coefficient values of variables are less than 0.85, then there are no multicollinearity issues in the model (Hunjra et al., 2020; Jiang & Ma, 2019; Krammer, 2010). Results of correlations indicate no multicollinearity issue as the coefficient value of all dependent variables is less than 0.85. Besides, we employed the VIF test which confirmed that our sample of the study has no multicollinearity issues as the value of the VIF test is lower than the standard limit of 5.

Tests	Breusch-Pagan LM		Pesaran scaled LM		Bias-corrected scaled LM		Pesaran CD	
Variables	Statistic	P-value	Statistic	P-value	Statistic	P-value	Statistic	P-value

Note: FD, REC, GB, IQ, GDP, and SEC represent financial development, renewable energy consumption, globalization, institutional quality, gross domestic product, and socio-economic conditions, respectively.

Note: Standard errors in parentheses at 1%, 5%, and 10% levels are *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$, respectively.

Further, to confirm the existence of cross-sectional dependency, we performed the CD test the results of which are reported in Table 4. Results indicate that null hypothesis of no-CD is rejected and alternative hypothesis for the existence of CD is accepted. In the presence of CD and heterogeneity, we also employed the second generation IPS (i.e., CADF) and CIPS unit root test to check the stationarity of the variables. Table 5 presents the CPIS and CADF results. Regarding CPIS test, CO₂, FM, GB, IQ, GDP, and SEC are stationary at level; however, REC is stationary at first difference. The CADF unit root test exhibits a mixed order of integration as FM, GB, and IQ stationary at level; however, CO₂, REC, GDP, and SEC are stationary at first difference.

Table 5. Pesaran CIPS Unit Root Test and Cross-Sectional Dependence Test

variables	CPIS			CADF		
	Level	1st difference	Order	Level	1st Difference	Order

Note: FD, REC, GB, IQ, GDP, and SEC represent financial development, renewable energy consumption, globalization, institutional quality, gross domestic product, and socio-economic conditions, respectively.

Note: Standard errors in parentheses at 1%, 5%, and 10% levels are *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$, respectively.

Table 6 presents the results of static and dynamic model of the study. However, we preferred a two-step system GMM (dynamic model) over a static model as it is consistent for output and the instrument's validity (tests for autocorrelation and over-identification). Similarly, specification tests confirm that two-step system GMM is appropriate for study as statistic results show that AR (1) = -2.110 is significant with p-value 0.0349, $p < 0.05$, 5%, whereas AR (2) = -0.729 is insignificant with p-value 0.466, $p > 0.05$, 5%. This indicates that the serial correlation test is unable to reject the null hypothesis of no second order autocorrelation. However, the null hypothesis of no first-order autocorrelation is rejected, which confirms that results are not affected by second-order autocorrelation. Similarly, the Hansen test value = 42.88 was insignificant with p-value 0.169, $p > 0.05$, 5%, implying that the null hypothesis fails to reject the instrumental validity and supports it. We also observed over the year the time effect of explanatory variables on carbon emission Appendix-D Table 10, which suggests CO₂ emissions increased in BRI countries over the year.

Based on the two-step system GMM results (column 5), FD is statistically significant at the 1% level with optimistic influence on CO₂ emission, which suggests that a 1% increase in FD can increase the CO₂ emission by 0.471% in BRI countries. This finding reveals that FD facilities offer low rate of borrowing with lesser restrictions for development projects. Consequently, low cost of financing encourages the private and household sectors to invest in new development projects (purchasing machinery and equipment) and durable goods (car, household appliance and other luxury items) which accelerates the energy demand and adversely affects impact on environmental quality. Besides, most countries under the BRI platform have low- or middle-income economy (developing countries). Therefore, unlike developed countries, they attempt to boost their economic growth while compromising on environmental quality (not focused on green finance or change in technology) (Charfeddine & Kahia, 2019; Wang et al., 2020; Zhang, 2011; Zioło et al., 2020).

Note: FD, REC, GB, IQ, GDP and SEC represent financial development, renewable energy consumption, globalization, institutional quality, gross domestic product and socio-economic conditions.

Note: Roodman, (2009) standards Stata Xtabond2 command, Standard errors in parentheses at 1%, 5%, and 10% levels are *** p < 0.01, ** p < 0.05, * p < 0.1, respectively.

Moreover, REC reports the estimated value of the coefficient as statistically significant and negatively correlated with CO₂ emission, indicating that a 1% change in REC can decrease CO₂ emission by −0.001% with a significance level of 5% in BRI countries. This finding is laudable and demonstrates that countries switching to REC can help improve the environment's quality by mitigating CO₂ emission. The world is shifting toward clean and green sources of energy, so it is important to employ advanced technology and an environmentally friendly sources of energy generation to create a sustainable environment. This result advocates the recent studies (Bao & Xu, 2019; Charfeddine & Kahia, 2019; Hao et al., 2021; Rahman & Velayutham, 2020; Uzar, 2020) identifying the significance of REC for a sustainable environment.

Similarly, GB, which is an essential determinant for climate change, indicates a significant and positive influence on the environment (CO₂) as 1% change in GB can reduce CO₂ emission by –0.003% with a significance level of 10% in BRI countries. It suggests that in BRI countries, GB connects countries which mitigates obstacles to making investments and trade. As a result, new technology can be imported and green investment opportunities created, which also improves the quality of the environment by reducing CO₂ emission. Moreover, increase in competition among GB firms' level encourages innovation and focuses on the latest techniques to improve the quality of products and services and address climate change issues. Our findings are consistent with previous studies (Jorgenson & Givens, 2014; Li et al., 2015; Shahbaz et al., 2016, 2017, 2019; Zafar et al., 2019; Zaidi et al., 2019).

Moreover, in the case of IQ, we have interesting findings for BRI countries. Results indicate that IQ is statistically significant and positively correlated with CO₂ emission, which suggests that in BRI countries, bad governance, weak bureaucracy, corruption, and improper implication of climate laws leads to increase in carbon emission. It is imperative for policymakers and concerned authorities to focus on institutional quality because better governance and implementation of law and policies improve environmental quality (Bhattacharya et al., 2017). The results of our study contradict those of past studies (Hunjra et al., 2020; Ibrahim & Law, 2016; Wang et al., 2018), however are in line with Godil et al. (2020) which reported that IQ quality had a negative influence on the environment in the case of Pakistan.

Finally, we also reported the findings of our control variables of studies that included GDP and SEC. The reported results in Table 6 indicate that GDP has an adverse effect on carbon emissions as a 1% change in GDP leads to 0.03% reduction in emission in BRI countries. This suggests that due to an increase in economic activities, demand of energy increases, which also causes carbon emission. Our findings are in line with previous studies (Charfeddine & Kahia, 2019; Shahbaz et al., 2013; Wang et al., 2020). Similarly, SEC is significant and positive in correlation with carbon emission, suggesting that SEC also causes environmental degradation in BRI countries.

Note: Financial development robust with sub-index financial markets and institution development. IQ (ICRG-Robust) represents the International Country Risk Guide Six alternate indicators of institutional quality. Globalization Index Robust with sub-index economic globalization. Human development index additionally added for robustness check.

Note: Roodman, (2009) standards Stata Xtabond2 command, Standard errors in parentheses at 1%, 5%, and 10% levels are *** p < 0.01, ** p < 0.05, * p < 0.1, respectively.

Moreover, to check the results' reliability, we conducted a robustness check using alternative proxies and a new variable. For instance, we adopted sub-indexes of FD which are the financial market and financial institutions index. Similarly, we used the sub-index economic globalization as an alternative proxy for GB and for IQ we used the ICRG as an alternative proxy for the robust check. Further we also introduced the human development index as a new variable for the robustness check.

For robustness check, we also employed a two-step system GMM to estimate the model as it effectively addresses the issues of endogeneity in the dynamic panel. The estimation results of the robust check are presented in Table 7, which indicates that all the explanatory variables of the study are consistent with the previous results. Alternative proxies for FD which are financial institutions and financial market are significantly positive in correlation with CO₂. Similarly, like previous findings, REC and GB (alternative proxy economic globalization) are negatively correlated with CO₂ emission. Moreover, IQ (ICRG-Robust), GDP, SEC has a positive relationship with carbon emission. Moreover, after the inclusion of human development as a robust variable, overall findings are in line with the previous findings.

Table 8. Results of Dumitrescu and Hurlin panel causality test

Null Hypothesis:	W-Stat.	Zbar-Stat.	P-value

CO2 → GDP	2.685	0.264	0.791
SEC → CO2	4.190***	3.754	0.000
CO2 → SEC	3.881***	3.038	0.002

Note: FD, REC, GB, IQ, GDP, and SEC represent financial development, renewable energy consumption,

globalization, institutional quality, gross domestic product, and socio-economic conditions, respectively.

Note: Standard errors in parentheses at 1%, and 5% levels are *** $p < 0.01$, ** $p < 0.05$, respectively.

Table 8 presents the results of Dumitrescu & Hurlin, (2012) non-causality test which was performed to explore the nexus of CO₂ emission with FD, REC, GB, IQ, GDP, and SEC. Results reveal a bidirectional or feedback causality relationship between FD and CO₂ which is in line with previous findings (Zaidi et al., 2019). Similarly, in the case of REC and CO₂, we also identified a bidirectional relationship running from REC to CO₂ and CO₂ to REC. However, CO₂ is Granger caused by GB and GDP which show a unidirectional causality relationship and are consistent with Zaidi et al. (2019). There is a bidirectional causality relationship between IQ and CO₂ and SEC and CO₂ for BRI countries.

4.1 Discussion of Results

The empirical results of this study can help scholars, policymakers, and governments of BRI countries. A comparative analysis between current and previous studies could help researchers and scholars to understand the role of two-step dynamic GMM modeling and (Dumitrescu & Hurlin, 2012) causality test with respect to investments, consumption pattern, global integration, governance, and environmental nexus. The study also employed CD test (Pesaran, 2004) and second generation unit root test (Pesaran, 2007) for determining cross-sectional dependence and stationarity of the data.

Table 6 presents the results of the dynamic and static model. However, due to the instrument's consistency and validity, we preferred a two-step system-GMM (dynamic model). The findings indicate that FD hurts environmental quality which is in line with previous studies (Charfeddine & Kahia, 2019; Wang et al., 2020; Zhang, 2011; Ziolo et al., 2020). Moreover, REC and GB help improve the quality of the environment in BRI countries which are consistent with previous findings (Bao & Xu, 2019; Charfeddine & Kahia, 2019; Hao et al., 2021; Rahman & Velayutham, 2020; Uzar, 2020; Jorgenson & Givens, 2014; Li et al., 2015; Shahbaz et al., 2016, 2017, 2019; Zafar et al., 2019; Zaidi et al., 2019). Further, IQ is negatively correlated with CO₂ emissions, which refer to bad governance, bad bureaucracy, corruption, and improper climate laws. It is in line with the findings of Godil et al. (2020). Results of the control variables GDP and SEC suggest that they deteriorate the quality of the environment. We also checked the robustness of the results by using alternative proxies and introducing new variables consistent with the main findings. Moreover, the causality relationship between the variables is presented in Table 8. A bidirectional causal relationship between FD, REC, IQ, and SEC on CO₂ emission was obtained. However, in case of IQ and GDP, we reported a unidirectional causal relationship with CO₂ emission.

5. Conclusion and Policy Implications

This study examined the impact of financial development (FD), renewable energy consumption (REC), on carbon emission (CO₂) with a dynamic role of Globalization (GB) and institutional quality (IQ) in belt and road imitative countries (BRI). The study used panel data of 64 BRI countries covering the period 2003 to 2018. We employed CD test (Pesaran, 2004) and CADF and CIPS unit root test (Pesaran, 2007), which confirms the cross-sectional dependence and stationarity of the variables. Moreover, the two-step system GMM technique is used to estimate the relationship between explanatory variables and CO₂ emission. The study's findings indicate that FD causes environmental degradation as financial institutions lend cheaper debts to the investors and household sector which boosts the economic activities and raise the energy demand and cause of CO₂ emission. However, due to the import of new efficient technology and switching toward green energy, RE and GB mitigate the CO₂ emission in BRI countries. Findings also confirm that weak governances, bureaucracy, implementation of climate law, and corruption, the role of IQ in BRI countries is negative in correlation with CO₂ emission. To examine the causal relationship between the variables, this study uses Dumitrescu and Hurlin's (2012) causality test. The Findings show that FD, REC, IQ, and SEC have a bidirectional causal relationship with CO₂ emission, however, GB and GDP have a unidirectional causal relationship with CO₂ emission.

Besides, this study also recommends the policy implication for scholars, policymakers, government officials, and other stakeholders of BRI countries, which are as follows:

- By allocating resources for socially responsible industries, investing in green government projects and restricting anti-ecofriendly technology and projects (taxes and penalties), the financial sector can become an essential tool for sustainable development in BRI countries. It is crucial for development banks to change the financial system and develop mechanisms to reduce the risk while mobilizing funds from the private sector,

play a role in making policies, and building capacity for green finance, and correctly identify the level of environmental risk in various projects.

- Another crucial factor is to encourage regional connectivity through globalization as it helps attract foreign investors for financing which brings innovation in production methods, new skills and knowledge, and advanced technology. Governments should adopt international environmental laws that encourage globalization to increase renewable energy in the total energy mix for a sustainable environment and economic growth.
- Energy is vital for the economy's growth, but it is also considered the second largest source of CO₂ emission. Therefore, the introduction of the renewable energy mix in the production line, import of efficient technology, R&D, and industrialization of the energy sector are key to mitigating CO₂ emission.
- The goal of environmental sustainability can only be achieved through good governance, eradication of corruption, transparency, quality of bureaucracy, and complete implementation of national and international environmental laws and policies in BRI countries. In other words, environmental quality depends on institutional quality.

This study has some limitations such as the sample of research based on BRI countries. In this study, we did not account for country-specific estimation and used carbon emission (dependent variable) per capita as a proxy of environment degradation. For future research, it is proposed that country-specify effects through non-linear estimation techniques and other proxies of the environment such as carbon footprint, greenhouse gases, or logical footprint might be employed.
