Abstract

Background: To evaluate the etiology of lacrimal canalicular laceration and explore possible risk factors influencing prognosis.

Methods: A total of 142 patients (142 eyes) with lacrimal canalicular laceration were reviewed and surgically repaired using canalicular anastomosis combined with bicanalicular stent intubation between March 2017 and March 2018. The analyzed data contained demographic information, types of trauma, injury location, associated additional ocular injuries and surgical outcomes at follow-up. The main outcome measures were anatomic success rate, functional success rate, and the complications of surgery.

Results: The mean patient age was 42.07 years (ranging from 1-75 years) and 112 (78.87%) were men. Upper and lower canalicular lacerations were found in 14 (9.86%) and 112 patients (78.87%), respectively, and both canalicular lacerations were found in 16 patients (11.27%). Electric bike accidents were the leading cause of injury with 76 patients (53.52%). There were 100 (70.42%) patients who had lid laceration without tarsal plate fracture and 42 (29.58%) patients who had lid laceration with tarsal plate fracture. Anatomic success rate was 98.59%, and functional success rate was 83.8%. Functional reconstruction failure rates were higher in patients with indirect injuries, lid laceration with tarsal plate fracture, and with punctum splitting ($P < 0.05$). Surgical Complications were detected in the form of lacrimal punctum ectropion in 3 (2.11%) patients, punctum splitting in 2 (1.41%) patients, stent extrusion and loss in 2 (1.41%) patients.

Conclusions: Electric bike accidents have become the leading cause of injury instead of the motor vehicle accidents because of changes in lifestyle. The indirect injuries, lid laceration with tarsal plate fracture and with punctum splitting, were significantly more likely to lead to a poor prognosis, as confirmed by the lower functional success rate of surgery.

Background

Canalicular laceration is commonly regarded as ocular emergency, caused by trauma in the eyelids and periorbital areas, frequently involving the lower canaliculus, have been reported in all age groups[1]. They are present in approximately 16% of all eyelid lacerations due to ocular trauma[2]. It has been reported that 72% of lower canaliculus occurs in monocanalicular laceration and that bicanalicular laceration occur in 6% to 24% of all canalicular injuries[3]. According to the mechanism of damage, Wulc et al. divided canalicular laceration into direct trauma like knife and dog bite injuries, and indirect trauma like blunt trauma[4]. It is reported that patients with canalicular laceration due to indirect or diffuse injuries were more than due to the presence of a penetrating injury[4].

The canaliculus can undergo stenosis, causing lacrimal drainage dysfunction with epiphora if not appropriately managed[5]. The canalicular anastomosis combined with bicanalicular or monocanalicular stent intubation is used for primary canalicular laceration repair[5]. A variety of materials have been used

to stent the torn canaliculus clinically, such as the medical-grade silicone stent[6,7], like the Freda[®] silicone tube, the mini-Monoka[®] [8], the Masterka[®] [9]. The mini-Monoka[®] is one of the monocanalicular stents, comprised of a silicon rod with a bulb and collar at the proximal end, which makes it self-retaining[8]. Mini-Monoka[®] insertion is suitable for conditions, such as canalicular laceration involving external two-thirds of canaliculus without damaging the canthal ligament. The silicone intubation is most commonly used in surgery based on its advantage of an inert nature, flexibility, and easy availability[6,7]. Several factors impacting the effectiveness of laceration repair include the extent and location of canalicular laceration, intubation materials, duration of intubation, and surgical technique[10,11,12]. The present study was conducted to review 142 patients with primary canalicular laceration in the department of Ophthalmology, Shanghai Ninth People's Hospital, China. We described the epidemiology and evaluated the etiology and prognosis of primary canalicular laceration repair using canalicular anastomosis combined with bicanalicular stent intubation.

Methods

Patients

We retrospectively reviewed the medical records of 142 patients (142 eyes) who had primary canalicular laceration and required surgical repair within 48 hours at the Department of Ophthalmology, Shanghai Ninth People's Hospital, Shanghai JiaoTong University school of Medicine, Shanghai, China, between March 2017 and March 2018. Most of the patients were initially referred to the emergency room, while the others were recruited from clinics. The retrospective study was performed with the approval of the Ethics Committee of Shanghai Ninth People's Hospital, Shanghai JiaoTong University school of Medicine, China. The informed consent and the commitment to follow up were signed by all subjects in our study, including the parents or guardians of the study participants who were minors at the time of study. These patients included 112 men, 30 women who were 1 to 75 years old (42.07years on average). Among these 142 patients, 134 received indirect injuries and 8 received direct injuries. The Patient demographics, affected canaliculus, number of canaliculus injured, nature of injury, and associated injuries were obtained through patient records, and the data on complications and surgical success rate were also collected for this study, as the post-surgery follow-up visits were recorded at 1.0 week and 1.0, 2.0, 3.0, 6.0 months after surgery. Exclusion criteria included the lack of adequate follow up(<3 months), preinjury epiphora and pyorrhea, additional lacerations involving the lacrimal sac and/or nasolacrimal duct or congenital and/or acquired lacrimal stenosis and/or obstruction.

Lacrimal system evaluation

We evaluated the lacrimal system before surgery and estimated whether the lacrimal system was involved when the eyelid laceration was very close to the medial canthus. Further examination of the lacrimal system was done by irrigation of the lacrimal canaliculus with a 2.0ml syringe of 0.9% saline solution under topical anesthesia. If the liquid flowed from the wound, a lacrimal probe was used to

confirm the position of the distal lacerated end of the lacrimal canaliculus, and the distance from the lacrimal punctum and then the distal lacerated end was measured.

Surgical procedure

Routine sterilization was provided and infratrochlear and infraorbital nerve block anesthesia were performed with 2ml 2% lidocaine and 2ml 0.75% bupivacaine for adults and general anesthesia for pediatric patients. The proximal lacerated end was found under a surgical microscope (ZEISS, Germany). Then a punctum dilator was used to enlarge the lacrimal punctum and bicanalicular silicone tube intubation was done using a 1.0-mm-diameter silicone tube with a probe at both heads (Shandong Freda Biotechnology Co., Ltd, China) as shown in Figure 1. One head was inserted into the ruptured canaliculus and nasal cavity, while the other end was placed into the upper or lower canaliculus and pulled out from the nasal cavity. The proximal and distal lacerated ends were subsequently anastomosed with 6–0 absorbable suture of polydioxanone (Johnson & Johnson, New Brunswick, NJ) around the silicone tube, and the meticulous re-approximation of the severed canaliculus was performed under an ophthalmic surgical microscope. The two corresponding ends of the silicone tube were tied securely with proper length. If any globe injury occurred, the globe wound repair needed to be performed before other management. Repairs of additional eyelid injuries were conducted after the lacrimal intubation. Preoperative and postoperative images of a typical case were provided in Figure 2. All repairs were performed by the same experienced surgeon.

Postoperative management

Antibiotics were simultaneously administered locally and intravenously to prevent infection. Post-surgery follow-up visits were recorded at 1.0 week and 1.0, 2.0, 3.0, 6.0 months. The silicone tube was shifted and checked monthly and extubation was performed 3–6 months after surgery followed by lacrimal irrigation. The surgery outcome was defined by lacrimal irrigation and the presence of symptomatic epiphora indoors.

Statistical analysis

Data were presented as mean \pm SD or *n* patients. The SPSS 22.0 software was used for statistical analysis. The clinical prognosis and surgical effect of canalicular laceration were compared with Chi Square test. Kaplan-Meier analysis and Cox proportional hazards regression analysis were used to determine risk factors influencing the prognosis of canalicular laceration. All *P* values were considered statistically significant when the values were < 0.05 .

Results

In our study, 112 (78.87%) of the patients were men, and 30 (21.13%) were women. The average age was 42.07 years (ranging from 1–79 years). A total of 88.7% (126) patients had one canaliculus involved. Sixteen patients (11.3%) had 2 canaliculi involved and no patients had 3 or 4 canaliculi involved. The

upper and lower canalicular laceration were found in 14 (9.86%) and 112 patients (78.87%), respectively, and both canalicular laceration were found in 16 patients (11.27%). The mean time interval between injury and surgery was 14.42 ± 0.36 hours (from 3-48 hours). The mean time of canalicular stent removal was 4.5 ± 0.54 months, and the mean follow-up period was 6.94 ± 0.51 months (Table 1).

The type of trauma that caused the canalicular laceration were shown in Table 1. Of all the patients, indirect canalicular injuries were detected in 134 (94.4%) patients, which were remarkably more frequent than direct injuries detected in 8 (5.6%) patients. Electric bike accidents were the leading cause of injury with 76 (53.52%) patients. The other mechanisms of injury were blunt injuries for 32 (22.54%) patients, car accidents for 10 (7.04%) patients, fights for 4 (2.82%) patients, falls for 12 (8.45%) patients, sharp objects for 6 (4.22%) patients, and dog bites for 2 (1.41%) patients, as shown in Table 1.

Other additional injuries associated with the trauma occurred in all the patients were also represented in Table 1. There were 100 (70.42%) patients who had lid laceration without a tarsal plate fracture and 42 (29.58%) patients with a tarsal plate fracture. Canalicular laceration combined with globe rupture had occurred in 6 (4.23%) patients of all the additional injuries. Some patients may have experienced 2 or more other additional injuries at the same time, while other injuries associated with trauma contained 14 (9.86%) extraocular muscle injuries, 10 (7.04%) head trauma, 7 (4.93%) ptosis, 2 (1.41%) optic neuropathies, and 2 (1.41%) vitreous and/or retinal detachments (Table 1).

All the canalicular lacerations were repaired during this study. The mean time of canalicular stent removal was 4.5 ± 0.54 months. During the follow-up visit, there was 2 patients with stent extrusion and loss because of a loose knot and patients had pulled the suture out. No patients had infection of the lacrimal canaliculus during the visit.

The surgery effects of canalicular laceration were presented in Table 2. After stent removal, patients were performed irrigation of lacrimal canaliculus, and asked about epiphora during follow-up. All 142 patients reflected anatomic success, besides 2 patients with stent extrusion and loss. Among these patients with anatomic success, 119 (83.8%) patients had functional success, claiming no epiphora. As shown in Table 2, among the upper, lower, and both canalicular laceration repair surgery, there was no significant difference between the anatomic success and functional success rate ($P > 0.05$; $P > 0.05$); the data also showed no significant difference in anatomic success rate between indirect and direct injury.

As shown in Table 2, the functional success rate was significantly lower in indirect injury than direct injury ($P < 0.01$); between canalicular laceration with and without tarsal plate fracture, there was no significant difference in anatomic success rate, whereas the surgery had a higher functional success rate in canalicular laceration without tarsal plate fracture than with tarsal plate fracture ($P < 0.01$); and between canalicular laceration with and without punctum splitting, no significant difference was shown in the anatomic success rate, however, the surgery had a higher functional success rate in canalicular laceration without punctum splitting than with punctum splitting ($P < 0.01$). About the surgery complications, we only found 3 (2.11%) patients with lacrimal punctum ectropion, as shown in Figure 3; 2 (1.41%) patients with punctum splitting as shown in Figure 4; and no patients had a false path.

The results of Kaplan-Meier analysis for treatment success rate are shown in Table 3, the Cox proportional hazards regression analysis of prognostic factors in canaliculus laceration repair surgery are also presented. Notably, canalicular laceration with indirect injury, tarsal plate fracture, and punctum splitting was significantly more likely to have a poor prognosis ($P=0.017$, 0.036 , and 0.045).

Discussion

Canalicular laceration is common in facial trauma and requires early intervention (within 48 hours) to restore anatomy and function in the ophthalmology department [4]. Men account for most of the canalicular laceration or about 78.87% in our study, which was similar to the results of 86% male cases reported by Naik et al [8]. In this study, patients with lower canalicular laceration involvement were the most common (78.87%). Liang et al. reported that 82.9% had lower canalicular lacerations 11.4% had upper canalicular laceration, and 5.7% had bicanalicular lacerations in their studies [13]. Our data corresponded with the findings of the above studies. Our mean time between injury and repair was 14.42 ± 0.36 hours (from 3-48 hours). Some authors hold that early treatment (9-32 hours) is the key to success in canalicular repair [8,14]. Tint et al. showed poor outcome in 6 out of 40 patients with delayed in repair (2-3 days) [14]. Chatterjee et al. reported that 5 patients who even presented between 2 and 4 days since injuries also had a successful outcome after surgery [15].

Although the epidemiology of canalicular lacerations had been published in some reports, the types of traumas causing injury were different due to change in lifestyle. In our study, Electric bike accidents became the leading cause of injury, with 76 (53.52%) patients, instead of motor vehicle accidents (35.81%), as in the past [16]. Electric bike has replaced motorcycle with the advantages of being inexpensive and providing environmental protection, with the increasing number of electric bike, the related rate of accidents is also increasing. We also found that patients with indirect canalicular injuries were remarkably more prevalent than those with direct injuries, which was similar to the results derived by Wulc et al [4].

Our studies showed that the rate of patients who had lid lacerations with tarsal plate fracture was 29.58%. As there was no previous data reported on the incidence of tarsal plate fracture during injury, we concluded that lid laceration without tarsal plate fracture was more frequent than that with tarsal plate fracture. In our study, globe rupture occurred in 6 (4.23%) patients. Herzum et al. reported a 20 to 44% incidence rate for globe injury in association with eyelid injuries [2]. These results are quite different from our own. Lee et al. later reported that traumatic hyphema and subconjunctival hemorrhage represent the most frequent associated ocular injuries instead of globe injury [17].

It was believed that the key to a successful surgical repair of canalicular lacerations was to find the proximal lacerated end quickly and precisely [18]. Many methods and skills to identify the proximal lacerated end of the canaliculus, such as the pigtail probe [19], upper canalicular probing, and injecting a bubble or colored opaque solution, have been shown in previous studies [17,18,20,21]. Silicone intubation was most commonly used in surgery because of its advantage of restoring a normal anatomical pathway

to avoid false path[5]. With double-passage canalicular intubation, circular stents using silicone tubes provide good stabilization, and keep the natural location of the medial canthus, maintain the physiological anatomical reposition of the superior and inferior punctum, which prevents the ectropion and laceration of the lower eyelid and inferior punctum, and offer excellent tear drainage[5,6,7]. However, it is reported that the disadvantages of double-passage canalicular intubation include the irritation symptoms and additional secretion[22]. All canalicular lacerations in our cases were repaired by double-passage canalicular intubation with successful anastomosis.

Among these patients, 140(98.59%) had anatomic success, while 119 (83.8%) patients had functional success. Kersten et al. described an alternative surgical approach for the repair of canalicular laceration using silicone tube intubation with a success rate of 96% based on lack of symptomatic epiphora[20]. Liang et al. reported that 91.18% of patients experienced complete success with complete disappearance of epiphora and 8.82% eyes achieved partial success after tube removal[13]. The results of ours were similar to the literatures reported above. Our results showed that certain factors, namely indirect injuries, lid laceration with tarsal plate fracture, and with lacrimal punctum splitting, lead to the lower functional success rate of surgery, and were the risk factors for canalicular laceration repair surgery; the reason may be the severe scarring surrounding the canaliculus due to the tarsal plate fracture and lacrimal punctum splitting.

In conclusions, the reasons for canalicular lacerations have changed because of changes in lifestyle. Our studies showed that certain factors, namely indirect injuries, lid lacerations with tarsal plate fracture and with punctum splitting, led to the lower functional success rate of surgery, and were the risk factors for functional reconstruction after repair surgery. A drawback of this study was its retrospective, noncomparative nature. However, a larger-scale study of a comparative nature is needed in the future. The results of this study will provide some suggestions for the prognosis of surgical treatment for canalicular laceration.
