Abstract

Background

Chronic lymphocytic leukemia (CLL) is a group of highly heterogeneous mature B cell malignancy with various disease courses and diagnoses. Super-enhancer(SE) is a novel concept drew in recent years which is a cluster of enhancers involved in cell differentiation and tumorigenesis ,and is one of the promising therapeutic targets for cancer therapy. Although there is a multitude of prognostic markers in CLL, insights into the role of super-enhancer(SE)-related risk indicators are still lacking.

Methods

The CLL-related super-enhancers in training database were processed by Lasso penalized Cox regression analysis to screen a nine-gene prognostic model. And the associations between all of the individual markers and OS of CLL were assessed by Cox regression analysis. Besides, in order to understand the connection between individual genes and selected disease characteristics, like IGHV mutation status, FISH abnormality, and ZAP70 expression level, we performed correlation analysis.

Results

A nine-gene prognostic model was screened, including TCF7, VEGFA, MNT, GMIP, SLAMF1, TNFRSF25, GRWD1, SLC6AC, and LAG3. A SE-related risk score was further constructed and the robust predictive performance with 5-year survival and time-to-treatment (TTT) area under the curve(AUC): 0.997 and 1.000 in the training database and 0.628 and 0.673 in the testing database, respectively. Besides, a high correlation was found between the risk score and known prognostic markers of CLL, including the mutational status of immunoglobulin variable region loci (IGHV), chromosomal abnormalities, and ZAP70 expression. Meantime, we noticed that the expression of TCF7, GMIP, SLAMF1, TNFRSF25, and LAG3 in CLL were different from healthy donors($P<0.01$), moreover, the risk score and LAG3 level of matched pairs before and after treatment samples varied significantly, although these results were not completely consistent in different datasets.

Conclusion

Therefore, the SE-associated nine-gene prognostic model developed here may be used to predict the prognosis and assist in the risk stratification of CLL patients in the future.

Background

Chronic lymphocytic leukemia (CLL), a mature and monoclonal CD5+ CD23+B cell malignancy, proliferates and accumulates in the bone marrow, blood, and lymphoid nodes(1). CLL cases are less in Asia than those in the western world, it is reasonable to assume that genetic and environmental factors play roles in pathogenesis(2). During 2014-2018, the rate of new cases of CLL was 4.9 per 100,000 per year and the median age at diagnosis is 72 years, the death rate was 1.1 (3).

CLL is widely known as a heterogeneous disease that exhibits variable clinical symptoms, time to treatment (TTT), progression, and prognosis. CLL patients are often diagnosed with incidental findings and the clinical course is ranging from an asymptomatic, indolent disease that requires no treatment to rapidly progressive and chemotherapy-resistant disease until death within a short period(2). The indications for treatment mainly include the clinical stage and symptoms of patients, and the standard therapy is chemoimmunotherapy. Unfortunately, the majority of CLL patients are too old to tolerate intensive standard chemotherapy, therefore, an effective prognostic model is needed to predict the individual clinical courses and to improve the outcome. Over the past few decades, huge advances have been made in figuring out the molecular and genetic biology of CLL to identify the indicators of progression and survival. These indicators include cytogenetics, age, IGHV gene mutation status, β 2-microglobulin (β 2-MG), clinical-stage (RAI/BINET stage), and so forth(4). In CLL, 13q14, 11q22-23 trisomy of 12q and 17p deletions are found in 80% of the cases. 11q22-23 and 17p deletions are associated with poor survival, whereas 13q14 deletions and trisomy of 12q have a longer TTT and survival time(5). TP53 aberrations(6) indicate a more aggressive disease progression and extensive drug-resistant and worse outcome, the same role applies to IGHV genes(7) and ZAP-70(8). Unmutated IGHV and high-expression of ZAP-70 have a comparatively aggressive disease course too, other relevant risk markers include expression of CD38(9), CD49d(9), lipoprotein lipase (LPL)(11), serum concentrations of thymidine kinase(12), and β 2-microglobulin(13).

Super-enhancer(SE), a new concept proposed for the first time in 2013, is a great cluster of adjacent enhancers that regulates gene expression, affecting cellular identity and the occurrence and progression of tumors. SEs regions include a large number of transcription factors (TFs), co-factors, and enhancer-associated epigenetic modifications(14). Mutation, rearrangement, and inducement of SEs themselves could lead to tumorigenesis and progression. Besides, some novel SEs inhibitors, such as BET inhibitor and CDK7i, which conduct clinical trials, have the potential to improve the tumor cure rate(15). In the hematopoietic system, several mechanisms of tumorigenesis that associated with SEs, including mutation, fusion, and controlling expression of specific genes, signaling pathways related to the tumor, even the infection of EBV.

In this article, a CLL-related SE-associated gene list is used to carry out Lasso penalized Cox regression analysis and construct a nine SE-associated genes prognostic model, namely, TCF7, VEGFA, MNT, GMIP, SLAMF1, TNFRSF25, GRWD1, SLC6AC, and LAG3. Meanwhile, this model is verified by training and testing datasets respectively. Univariate and multivariate Cox regression analysis and ROC curve are analyzed to evaluate the prognostic accuracy of this nine-gene model. Besides the above-validated steps, the role of the nine-gene prognostic model and the nine hub genes are further explored in CLL genesis and the relationship between this prognostic model and other known risk markers, like IGHV status, FISH abnormality, ZAP70 expression level. Finally, paired pre-and post-treatment datasets are used to examine the influences of treatments in the risk score or each nine hub genes expression. It is indicated that the model demonstrates predictive power and has an expected relationship with known risk markers. The improved nine-gene prognostic model of this work provides a bright future for the diagnosis, therapy, and disease stratification of patients with CLL.

Methods

Data Source and Microarray Analysis

The microarray data and clinical data of GSE22762(16) and GSE39671(17) which contain 107 and 130 CLL patients respectively were downloaded from Gene Expression Omnibus (GEO) database. These data were conducted by GPL570 and GPL96/GPL97. Here, 9 other datasets were also analyzed for different purposes, and the details were performed in Table 1(18-24).

Lasso Penalized Cox Regression Analysis

Super-enhancers-related genes list figured from the Primary B-CLL cell was downloaded from SEA version 3.0 which enriched with a post-translational modification histone mark, H3K27ac ChIP-seq signal. The gene matrix for subsequent analysis was obtained from the overlapping apart of genes in the GSE22762 dataset and the SE-associated genes in the Primary B-CLL cell. For narrowing and selecting the prognostic genes with potentiality, the overlapping gene matrix was weighted by the relative coefficients through the Lasso penalized Cox regression. Ten-fold cross-validation derived the best-fit lambda value to decrease the mean cross-validated error as much as possible via the R package "glmnet". We chose one median parameter to establish one ideal prognosis model. Then we measured time-dependent ROC curves and calculated the area under the ROC (AUC).

Risk Score Model establishment on Predicting Patient Overall Survival

After Lasso penalized Cox regression analysis was carried out, a risk score model was built using above nine genes, and could calculate a risk score for each sample through this formula: Risk score = . Patients were separated into high- and low-risk cohorts (median risk score) using the R software 'survival' and 'survminer' packages and a t-test was used to distinguish death and survival events according to the risk score.

Cox Proportional Hazard Regression Model

Univariate Cox hazard regression analysis validated the correlation among the expression levels of nine genes and OS of each patient by the R package "survival" and "survminer". At the same time, multivariate Cox hazard regression analyses were performed too. We foresaw the regression coefficient (β -value) and HR. The K-M survival curve and log-rank test of every single gene was also performed by the R package referred to above.

WGCNA

Weighted gene co-expression network analysis (WGCNA) screened SE-associated hub genes differentially expressed between healthy donors and CLL patients. We counted out the optimal soft-thresholding value under the scale independence and mean connectivity analysis. CLL-related genes were clustered into

various modules and gained an intersection of significant models and SE-related gene lists via Venn diagrams.

Gene set enrichment analysis

Under the standard of risk score, we separated the participants into high- and low-risk group sets. Kyoto Encyclopaedia of Genes and Genomes (KEGG) analysis revealed a potential signaling pathway underlying the two sets via Gene Set Enrichment Analysis (GSEA v4.1.0 software). $p < 0.05$ and a false discovery rate $q < 0.25$ were thought to be vital in the statistic.

Statistical analysis

SPSS software version 25.0 (SPSS, Inc., Chicago, IL, USA) and R software version 3.6.3 (R Foundation for Statistical Computing, Vienna, Austria) analyzed the data in statistics. A two-sided $p < 0.05$ was thought vital in a statistic.

Results

Construction and Validation of Nine-gene Lasso Penalized Cox Regression Model

The flowchart features the construction and validation of the SE-associated gene-based prognostic model of CLL and the correlation with other known risk markers (Figure 1). 831 primary B-CLL cell-related SEs list is downloaded from the website and the 18887 genes matrix in CLL patients is provided in the GSE22762 column and a 587 SE-associated genes matrix for CLL is gained via overlapping above two gene sets. Immediately after, the gene matrix is done by Lasso penalized Cox regression to screen the prognosis-related genes with potentiality. Figure 2A shows the coefficient values for each at various penalty levels. As long as genes with non-zero coefficients has prognostic value in the Lasso penalized regression model. Ten-fold cross-validation obtains the maximum lambda value and we select one model which produced a group of nine genes (Figures 2B). Principal component analysis (PCA) shows high-risk patients separate from low-risk ones evidently (Figure 2C). And the obvious distinction between survival and death is calculated by using the nine gene-based prognostic model, implying that the prognostic model functioned smoothly in the prediction on the OS of patients with CLL (Figure 2D).

Validation of Independent Prognostic Factors by the Cox Regression Model

To validate the Lasso penalized Cox regression model, univariate Cox proportional hazard regression analysis determines that these genes affect the OS of patients with CLL independently and all log-rank p -values of the nine genes are < 0.01 (Figure 3A). Following multivariate Cox proportional hazard regression analysis is performed too, and the global p -value of our model is only $2.64e-16$ (Figure 3B), the AIC was 124.96, and the C-index was 0.95, these indexes suggest that the nine genes possibly prognostic markers in favor for the OS of CLL patients. Meanwhile, the results of the K–M survival analysis show that GRWD1, SLC6A3, MNT have no significant association with survival (Supplement Figure 1). Furthermore, followed above hazard ratio of uni- and multivariate regression analysis, SLAMF1, TCF7, TNFRSF25,

MNT, and VEGFA are protective factors, whereas GRWD1, SLC6A3, GMIP, and LAG3 appear to be harmful factors in CLL. Thus, the nine-gene SE-associated model by Lasso penalized Cox regression possibly predicts the OS of CLL patients.

Establishment and Validation of the Nine gene-based Risk Score Model

107 patients in the training dataset of GSE22762 (HGU-133plus2) were divided into high-risk (risk score > 0.7) and low-risk groups (risk score < 0.7) (Figure 4A). Figure 4B presents that death is more frequently observed in the high-risk group set than the low-risk group. The K–M survival analysis presents a much worse outcome in the high-risk group than that of the low-risk group (log-rank test, $p = 3.561 \times 10^{-9}$) (Figure 4C). And the AUCs of a time-dependent ROC curve of 1-, 3- and 5-year calculated by the nine gene-based risk score model are 0.997, 0.958, and 0.996 respectively (Figure 4D), suggesting that the prediction is highly sensitive and specific. The testing column (GSE22762, N=44, HGU-133A) verifies the predictive values of the nine gene-based risk score. K–M curve of high- and low-risk are noticeably different (log-rank test, $p < 0.05$), and AUCs of 1-, 3- and 5-year ROC curves are 0.738, 0.679, and 0.628, these results show that this prognostic model might be a potential predictor to judge the OS of patients with CLL (Supplementary Figures 2).

Gene Set Enrichment Analysis

GSEA is carried out in two datasets on exploring enriched KEGG pathways of which the analysis suggests that vital enrichment is concentrated in the high-risk cohort including base and nucleotide excision repair, DNA replication, and valine-leucine and isoleucine degradation (Figure 5A, B). Other pathways including homologous recombination, oxidative phosphorylation, mismatch repair, RNA degradation, RNA polymerase, and one carbon pool by folate and lysine degradation are enriched in the high-risk group of the two cohorts.

The prediction of the nine-gene model on TTT

In addition to survival, we also investigate the nine-gene prognostic model on time to treatment (TTT) and the results demonstrate that the nine-gene risk model performs well on predicting TTT in the training data set (GSE22762). Low-risk patients own a longer TTT than high-risk patients and the p -value < 0.001 (Figure 6A). Additionally, the time-dependent ROC curve analysis prompts that the AUCs of 1-, 3-, and 5-year TTT are 0.818, 0.840, and 1.000, respectively (Figure 6B). These results are in accordance with testing datasets (GSE39671) (Figure 6C, D), and it indicates that the prognostic model is equally effective in predicting TTT.

Identification of SE-Related Hub Genes in CLL Using WGCNA

Besides the prognostic value, we also expect there is any relationship between the nine-gene model with tumorigenesis. Weighted gene co-expression network analysis (WGCNA) is another statistical method for the analysis of finding the different genes between normal and CLL patients. As showed in Figure 7A, the best soft-thresholding value via prediction of the scale independence was $\beta = 6$. Then, genes were divided

into 9 different modules with 9 different colors and a heat map was developed according to Pearson's correlation coefficient (Figure 7B). An intersection between the SEs matrix and the nine modules which presented a higher correlation with CLL showed that TCF7 and LAG3 appeared in the interaction genes between module purple, yellow, and SE-associated genes (Figure 7C). Simultaneously, TCF7, GMIP, SLAMF1, TNFRSF25, and LAG3 are found to express differently in normal and CLL patients when we compared the individual expression of nine SE-related hub genes in CLL (Figure 7D). The data indicates that the five genes may play a vital role in regulating the genesis of CLL.

Nine-gene prognostic model and other known risk factors

The performance of the nine-gene prognostic model is additionally evaluated in different subgroups defined by confirmed risk factors. Patients with mutated IGVH genes, 13q14 or single deletion or trisomy 12 on FISH analysis represent a favorable outcome, whereas patients with unmutated IGVH status, 17p13 or a 11q23 deletions have an unfavorable prognosis. Unmutated IGHV patients have a higher risk score than mutated IGHV patients in three independent datasets (GSE9992, GSE16746 and GSE28654) (Figure 8A-C). Simultaneously, we analyze the correlation between IGHV mutation status and each gene in the nine-gene prognostic model. The results report that the expression of TCF7 and SLAMF1 has a strong positive correlation, and LAG3 shows a negative correlation with IGHV mutation (Figure 8D). Similarly, patients with del17p13 have a higher risk score compared to other chromosome types ($p < 0.001$, Figure 8E). The risk score of ZAP70-high patients is higher than ZAP70-low patients and the expression of MNT and SLAMF1 have a negative association, LAG3 has a positive association with ZAP70 respectively (Figure 8F, G). Besides, the variation of risk score and each gene expression before and after treatment is provided in Supplement Figure 3A. The risk score is downregulated after processing with HDAC inhibitory in vitro, and VEGFA and MNT are upregulated accompanied by downregulated GMIP and TNFRSF25. In the other two in vivo treatment experiments, no significant change is found except LAG3, the LAG3 gene is upregulated consistently after lenalidomide and thalidomide treatment respectively (Supplement Figure 3B, C).

Discussion

Super-enhancer(SE) is a new concept drew in recent years, a growing body of evidence indicates an explicit relationship between increasing tumorigenesis and malignancy of cancer and SEs. SEs drive not only the expression of genes but also non-coding RNA that regulate biological functions directly and indirectly. Lasso penalized Cox regression is popular in recent years cause it could minimize overfitting(25). Hence, in our article, we use this novel bioinformatic strategy and the Cox proportional hazard regression models to screen and optimize hub genes related to survival.

CLL, is considered to have a highly heterogeneous clinical course, with time to first to treatment is varying from months to years, and many patients eventually progressing and requiring chemotherapy, although initially, CLL is reported as an indolent malignancy. A review of the data so far, disease stratification, IGHV mutation status, 17p- and ZAP70 expression are the validated prediction of overall survival. Beyond that,

gene expression analysis was carried out in various surrogate markers for genetic features and prognosis. Six surface antigens(CD62L, CD54, CD49c,CD49d, CD38, CD79b) prognostic risk model was put in place to diagnose and predict the OS for CLL(26). Besides, some large-scale gene expression profiling analyses generate different prognostic factors(16, 27, 28). But the before studies constructed no prognostic model according to SEs-associated genes which regulate the expression of hub genes related to CLL tumorigenesis.

In our research, the Lasso penalized Cox regression analysis is carried out by filtering out the potential SE-associated genes and yield a nine-gene prognostic model to foresee the OS of CLL patients. All of the individual markers in the nine-gene model associated with OS of CLL by Cox regression analysis results identical. K-M survival analysis also indicate that the majority of the nine genes correlated to OS. Beyond that, the nine-gene prognostic model is highly significant in the multivariate analysis of patients without treatment. The AUCs and C-index show that our model perform well in the prediction of survival. The effectiveness of this prognostic model could be validated by an independent patient cohort. Besides OS, this risk model is another indicator of TTT. We utilize the Nine-gene risk score in the GSE22762 and GSE39671 dataset and the results also indicate that the nine-gene model could be applied to predict TTT, the high-risk patients had less time to treatment than that of the low-risk. These data strongly indicate that the nine-gene prognostic model is a significant and valid risk forecaster.

We not only evaluate the data by a rigorous training and validation design, but also concentrate on the connection between individual gene and selected disease characteristics, like IGHV mutation status, FISH abnormality, and ZAP70 expression level. The results of three of the markers(TCF7, SLAMF1, and LAG3) are detected according to the association with IGHV status is expected. The lack of a public database that includes both survival data and mutation information limits the further research in a correlation between the nine-gene model and IGHV status. The same situation has occurred in studying ZAP70 and FISH abnormality. But in the poor prognosis group, like ZAP70-high and 17q- patients, the nine-gene risk score is significantly high than the low-risk group and we find that low expression of SLAMF1 in CLL is associated with ZAP70-high expression. The quantitative relation between TCF7, LAG3, and SLAMF1 expression and inferior overall survival is an accurate finding and indicates that these genes have a pathogenic role in CLL. Attended by that, the nine-gene prognostic model also play an important role in CLL etiopathogenesis. The WGCNA of the GSE50006 dataset reveals that TCF7 and LAG3 belonged to two gene module respectively, in addition to this, the expression of GMIP, SLAMF1, and TNFRSF25 are also significantly different in normal and CLL patients. Therefore, the five genes contained in our model are possibly functionally vital in the pathogenesis of CLL. In the present study, SLAMF1, TCF7, TNFRSF25, MNT, and VEGFA are protective factors, whereas GRWD1, SLC6A3, GMIP, and LAG3 appear to be harmful factors in CLL, we subsequently discussed each gene in the prognostic model.

Transcription factor 7 (TCF7), the T-cell-specific transcription factor required for T-cell development, animal models, suggested that it probably functions as a tumor suppressor(29). TCF7 over-expression in mice led to a disease resembling CLL, indicating that it was probably involved in the CLL transformation in direct(30). In CLL, TCF7 expression provided a high rate (74%) of correct assignment of patients at

genetic risk (IGHV unmutated, V3-21 usage, 11q- or 17p-)(28). The above results are consistent with ours and this indicated TCF7 was an important role in CLL.

Signaling lymphocytic activation molecule family member 1 (SLAMF1), also known as CD150), regulates hematopoietic stem cell differentiation, leukocyte adhesion and activation, and humoral immune responses. SLAMF1 comparatively over-express in normal peripheral blood B cells according to before meta-analysis of three gene expressions profiling studies. Recently, researchers found lower levels of SLAMF1 expression in cases with ZAP70-high ($p < 0.001$), IGHV-unmutated ($p < 0.001$), 17q- ($p = 0.003$). In past studies, we believed that loss of SLAMF1 expression in CLL modulates genetic pathways regulated chemotaxis and autophagy and that potentially affected drug responses, suggesting that the effects underlie unfavorable clinical outcomes experienced by SLAMF1-low patients(31). Together, SLAMF receptors, the vital modulators of the BCR signaling axis, improve immune control in CLL by interference with NK cells in potential(32). In our research, the univariate and multivariate analysis presented that down-regulated SLAMF1 levels had an independent negative prognostic impact on overall survival ($P < 0.05$). We subsequently discovered that SLAMF1 is relatively overexpressed in IGHV mutated and ZAP70-low CLL patients. The strict correlation among low levels of it and high-risk genetic features indicated that it probably represented a marker that surrogate genomic complexity, however, mechanism of this correlation is still unknown.

Lymphocyte activating gene 3 (LAG3), the immune inhibitory checkpoint receptor, is one of the immunoglobulin superfamily with about 20% amino acid homology with CD4. The expression of it activates and exhausts T, NK cells, B cells, dendritic cells, and regulatory T (Treg) cells. LAG3 high expression in CLL cells correlates with unmutated IGHV ($P < 0.0001$) and decreased treatment-free survival ($P = 0.0087$)(33). Increased LAG-3 expression on leukemic cells correlates with shorter time to treatment and poor outcome in CLL, moreover, treatment with relatlimab, a novel anti-LAG-3 blocking monoclonal antibody currently under clinical trial for different solid and hematological malignancies including CLL, restored, at least in part, NK and T cell-mediated anti-tumor responses(34). CART cell generation with the showing of ibrutinib created enhanced cell viability and expansion of CLL patient-derived CART cells. And ibrutinib enriched the mentioned cells with the less-differentiated naïve-like phenotype and declined expression of exhaustion markers (PD-1, TIM-3, and LAG-3)(35).

Vascular endothelial growth factor A (VEGFA), a member of the PDGF/VEGF growth factor family. The angiogenesis process makes a significant contribution to the pathogenesis of B-cell chronic lymphocytic leukemia (B-CLL) being the levels of VEGFA and bFGF higher in patients than in healthy(36). Whereas, in our research, VEGFA has a protective role in CLL. High expression of VEGFA indicated a good prognosis by K-M survival analysis, and in normal samples, the level of VEGFA was higher even though it was not statistically significant.

TNF receptor superfamily member 25 (TNFRSF25), the receptor expresses preferentially in the tissues in lymphocytes and possibly functions vital to the regulation of lymphocyte homeostasis. The receptor stimulates sNF-kappa B activity and regulates cell apoptosis. TNFRSF25 was differentially expressed

activating CLL cells and predominantly detecting in those with early clinical stage disease(37), and probably alters the balance between cell proliferation and death, influencing CLL physiopathology and results in the clinic.

Three genes (GRWD1, GMIP, and SLC6A3) have not been described in the context of CLL before and all of them were upregulated in high-risk CLL patients. The results of the univariate and K-M survival curve were not completely consistent with multivariate analysis. Glutamate rich WD repeat containing 1 (GRWD1), was identified as one of the ribosomal/nucleolar proteins that promote tumorigenesis(38). Meanwhile, GRWD1 was also viewed as having histone-binding activity and regulating chromatin openness to specific chromatin locations(39). Overexpression in colon carcinoma tissues was related to pathological grading, tumor size, N stage, TNM stage, and poor survival, knockdown of GRWD1 function as an inhibitor on cell proliferation and colony formation, and induced cell cycle arrest and more drug susceptibility, and suppressed the migration and invasion(40). GEM interacting protein, a RhoA-specific GAP, in a proteomics screen for proteins interacting with Girdin (Girders of actin), an actin-binding protein critical for neuronal migration to the olfactory bulbs, is identified as one of the major regulators of neuronal migration in the postnatal brain(41). Solute carrier family 6 member 3 (SLC6A3) involving in the metabolism of dopamine and catecholamine is the gene for Parkinson's disease and alcoholism in potentiality. The significance of the above three genes in CLL remained to be further studied.

In GSE14973, the risk score was significantly down-regulated after the valproic acid (VPA) treatment in vitro, meantime, protective factors (VEGFA and MNT) were high-expressed and pathogenic gene (GMIP) was low-expressed than before treatment, except TNFRSF25, and these results were almost consistent with our previous conclusion. VPA, a well-tolerated anti-epileptic drug with HDAC inhibitory activity. HDAC1 and HDAC3 inhibition or knockdown results can be figured out in HDAC7 downregulation which is related to a decline in histone 3 lysine 27 acetylation (H3K27ac) at transcription start sites (TSS) and super-enhancers (SEs) prominently in stem-like BrCa cells. In GSE112953 and GSE15913, the only upregulated gene was LAG3, and it may prompt that combination drug treatment with anti-LAG3 monoclonal antibody would receive a better outcome.

A limited set of gene expression markers was of independent prognostic value and thus increased the accuracy on predicting overall survival and time to treatment, while we couldn't compare the predictions from the model to the individual factors in the clinic, like IGHV somatic mutation status, stage, and other clinical data because of incomplete data; future studies should address this well, and more large cohort studies are needed to validated our model.

Conclusion

To sum up, it is the initial study using the Lasso model to screen prognostic indicators from the profile of SE-associated genes in CLL. A fruitful prognostic score for OS in untreated CLL patients is presented and the determination on the score can be achieved via the measurement of the expression levels of nine

genes. It also can do easily in a routine diagnose. In addition, the nine genes in this model are potentially SE-associated genes for CLL, functioning vital in the development and progression of CLL.

Tables

Table 1. The details of databases used in this research.

GEO accession	Number	subgroup of samples	Sample type	application in article
GSE22762[15]	151	151 CLL	PBMC	Establishment of survival model by Lasso and survival analysis of OS and TTT by nine-gene model
GSE39671[16]	130	130 CLL	PBMC	survival analysis of TTT by nine-gene model
GSE50006	210	188 CLL 32 healthy donors	CD19+ B cells	Validation for expression difference of hub genes between CLL and healthy donors
GSE9992[17]	60	24 M-CLL 36 U-CLL	CD5+CD19+CD23+ B cells	Validation for the correlation of hub gene expression and risk score with IGHV status
GSE16746[18]	60	23 M-CLL 37 U-CLL	CD5+CD19+CD23+ B cells	Validation for the correlation of hub gene expression and risk score with IGHV status
GSE28654[19]	89	61 M-CLL 28 U-CLL	CD19+ cells	Validation for the correlation of hub gene expression and risk score with IGHV status
GSE25571[20]	109	FISH abnormality	PBMC	Validation for the correlation of hub gene expression and risk score with genotypic abnormality
GSE12734[21]	14	7 high-ZAP70 7 low-ZAP70	CD19+ cells	Validation for the correlation of hub gene expression and risk score with ZAP70 expression level
GSE14973[22]	28	14 CLL with and without VPA	B cells	Validation for the correlation of hub gene expression and risk score with before and after treatment
GSE112953	22	11 CLL before and after Lenalidomide treatment	CD19+ cells	Validation for the correlation of hub gene expression and risk score with before and after treatment
GSE15913[23]	40	20 CLL before and after thalidomide treatment	PBMC	Validation for the correlation of hub gene expression and risk score with before and after treatment

CLL, Chronic lymphocytic leukemia; PBMC, peripheral blood mononuclear cells; M-CLL, IGHV mutated CLL; U-CLL, IGHV un-mutated CLL; OS, overall survival; TTT, time-to -treatment

Figures

Figure 1

A flowchart of the overall procedure used to establish and verify the SE-associated gene-based prognostic model in CLL patients.

Figure 2

Construction of the SE-related prognostic model. (A) The lasso coefficient values at various levels of penalty, each curve represents a SE-gene. (B) The confirmation of the best lambda value by lasso Cox regression analysis. (C) Principle component analysis(PCA), red dots correspond to high risk patients, blue dots correspond to low risk patients. (D) The scatter plot of survival status of CLL patients based on 9-genes model using the t-test. ***, $p < 0.001$.

Figure 3

Univariate and multivariate Cox regression analyses of the SE-related nine-gene prognostic model. (A) Univariate Cox regression analysis of the each gene of the model. (B) Multivariate Cox regression analysis of the nine-gene model. *, <0.05, **, p<0.01, ***, p<0.001.

Figure 4

The nine-gene prognostic model for the GSE22762 dataset (N=107, HG-U133_Plus_2). (A) Dot plots comparing outcomes of subjects in the high- and low-risk cohorts. (B) The survival status and time in high- and low-risk group. (C) K-M survival curves showing the difference between high- and low-risk group. (D) Time dependent ROC curve analysis for the prediction survival using the nine-gene model. K-M, Kaplan-Meier; ROC, receiver operating characteristic; AUC, area under the curve.

Figure 5

Pathways with significant enrichment in each dataset. The top 10 pathways were enriched in the training dataset (A) and validation cohorts (B).

Figure 6

The prediction of TTT on CLL patients. (A)(C) K-M survival curves showing the different TTT on two datasets and (B)(D) ROC analysis for the prediction of TTT.

Figure 7

Identification of SE-related hub gene in CLL based on GSE50006 dataset through WGCNA analysis. (A) Analysis of the scale independence and mean connectivity (vertical axis) for various soft-thresholding powers (β value of horizontal axis). (B)(C) Heatmap of the correlation between modules and CLL. The yellow and purple module had a high correlation with CLL patients and the p-value in the table specified the correlation. TCF7 and LAG3 appeared in the intersection of SE-related genes and the two modules, respectively. (D) The nine hub genes expression was significantly different between normal and CLL patients in GSE50006 dataset. **, $p < 0.01$; ***, $p < 0.001$.

Figure 8

Correlation and variances between the risk score or each gene expression and well-established prognostic markers of CLL. (A)(B)(C)The risk score of patients with IGHV mutation was significant lower than patients without mutation in GSE9992, GSE16746 and GSE28654. Nor, normal; Mut, mutation. (D) The correlation analysis of nine hub genes expression and IGHV mutation statue. The p-value in red box <0.001 respectively. (E) The risk score of patients with del17p13 was significantly higher than other

chromosome abnormalities. ***, $p < 0.001$. (F)(G) The different level of risk score in high- and low-ZAP70 patients and the correlation between nine hub genes expression and ZAP70 level.
