Abstract: Taking dolomite and limestone in Guilin and Liuzhou regions in the north of Guangxi Province as research objects, this paper analyzed their mineral composition and chemical composition, and then carried out the chemical corrosion test, the corrosion test under the chemical-temperature actions, and the corrosion test under the action of vibration load, respectively. The results showed that: (i) the dolomite in northern Guangxi mainly has fine crystalline texture and massive structure with low content of acid insoluble matters, while limestone mainly has powder crystalline texture and massive structure with high content of acid insoluble matters, and the purity of both dolomite and limestone are very high; (ii) the difference of corrosion between dolomite and limestone mainly depends on the ratio of CaO/MgO in their chemical composition, and the content of silica and acid insoluble matters; (iii) the corrosion rates of the pure dolomite and the pure limestone are basically the same under the same external conditions; (iv) temperature and vibration load have relatively large influence on the corrosion rates of dolomite and limestone, and the corrosion rates of dolomite and limestone increase with the increase of temperature, but the influence of vibration load on the corrosion rate is more significant than temperature. This research can provide theoretical basis and technical support for large-scale engineering construction and prevention of karst geologic disasters in karst stone mountainous areas in the northern Guangxi.

Keywords: dolomite and limestone; structural features; corrosion characteristics; northern Guangxi

1. Introduction

In carbonate rock areas, due to the differences in mineral composition and chemical composition of rock mass, the differences in internal structure and pore characteristics, and the influence of external conditions such as groundwater occurrence, temperature and vibration load, the dolomite and limestone distributed in these areas have differential corrosions. The differential corrosions often destroy the integrity of the rock mass, affect the mechanical properties and stability of the rock mass, and have a great impact on the safety of buildings and constructs attached to it. China's karst landforms are widely distributed with a large area, and mainly distributed in Guangxi, Guizhou, and eastern Yunnan. It is one of the largest karst areas in the world, with large continuous limestones and dolomites distributed. With the continuous reinforcement of China's economic strength and the continuous advancement of the development strategy in Southwest China, the strategic planning of "Silk Road Economic Belt" and "21st Century Maritime Silk Road", urban railway transits, underground utility tunnels and other infrastructure constructions have achieved unprecedented development, and numerous large-scale infrastructures such as high-speed railways and highways have been started in Southwest China one after another. Due to the complexity of geological structure in Southwest China, engineering geological problems have appeared in most projects, among which karst geologic disasters are overriding. The wide range of karst distribution has seriously hindered the development of transportation infrastructure in Southwest China. Therefore, it is of great engineering practical significance to profoundly study the structural characteristics and differential corrosions of the limestone and dolomite.

The research on karst geologic disasters is mainly divided into two categories: theoretical research on corrosion mechanism and research on karst detection methods. The corrosion test of carbonate rocks is an important content of the theoretical research. Scholars in the past have done a lot of experiments on the corrosion characteristics of carbonate rocks, and have achieved many results. Liu *et al.* (2018) used the two-scale continuous medium model to simulate the dissolution reaction process and predict the optimal injection rate during acidification treatment of carbonate rocks, and put forward a general numerical method to simulate structured

and unstructured reaction flow problems. Zhao *et al.*(2018, 2017) proposed a new alternative method for theoretically dealing with the evolution process of chemical dissolution surface in water-saturated porous rocks when propagating in a chemical system. In this method, porosity, pore fluid velocity and acid concentration were taken as independent variables, so that the problem of water-rock interaction could be solved by numerical methods and algorithms. Liu *et al.* (2013) studied the infiltration and corrosion change process of carbonate rocks under different dynamic water pressure conditions, and the results showed that the infiltration and corrosion along the internal pores of rocks had an important influence on corrosion rate. Liu *et al.* (2015) analyzed the characteristics of carbonate rocks in Shibing area of Guizhou from macro- and micro-perspectives, focusing on the investigation of influence of differential weathering of limestones and dolomites on the causes of avalanche, stone peaks, and rocky desertification. She *et al.*(2014) studied the morphology of carbonate rocks after corrosion by scanning electron microscope (SEM), and found that although the mineral composition and content of carbonate rocks have certain influence on their corrosion, the types and connectivity of pores formed after the corrosion are more closely related to the formation of favorable carbonate rock reservoirs. Wei *et al.*(2013) studied the corrosion of rocks containing dolomitic limestone and dolomitic limestones from different corrosion time scales. Under the same pH value and the same corrosion time, the corrosion rate of dolomitic limestones is higher than that of rocks containing dolomitic limestone. Zhang *et al.* (2012) revealed that the rock microstructure plays a controlling role in the corrosion rate, and the corrosion rates of dolomites with different structures are as follows: mesocrystalline to fine crystalline dolomites > fine crystalline to powder crystalline dolomites > powder crystalline to micritic dolomites; the specific surface area is related to the total corrosion amount, but independent of the corrosion rate per unit surface area. The corrosion starts from intergranular and intercrystalline pores, structural microfractures and cleavage, and gradually expanded to make pores and fissures connected with each other. The above researches on the corrosion investigated the corrosion characteristics of limestones and dolomites from the aspect of water-rock interaction mechanism with the consideration of the influence of

lithology, the characteristics of acidic solution and microorganisms, *etc.*, which provides a theoretical basis and practical reference for the research of this project. On the basis of the above research results, taking the action factors of temperature and vibration load into account can further confirm and improve the above research conclusions and would be more in line with the actual situation, so it has certain feasibility and important significance.

Temperature is one of the important factors affecting the mechanical properties of rocks. Rock is composed of solid mineral particles and tiny gaps between the particles. The solid mineral particles and the channel networks formed by gaps between the mineral particles are often filled with fluid media. When changes in the environment of such porous media of rocks occur, the water presenting in the pores and fissures inside the rocks will undergo phase change, leading to changes in the physical and mechanical properties of the rocks. These changes are not only related to their physical structure, but also affected by the existing water, temperature and stress state in the rocks. A lot of researches have been done on this influence at home and abroad. Nomeli *et al.* (2017) used a kinetic model extended based on the standard arrhenius equation to study the corrosion rate of calcite in the temperature range of 50-100 °C and the pressure up to 600 bar, and determined the functional relationship between calcite dissolution and temperature, pressure and salinity. Eliwa *et al.* (2017) studied the thermodynamics and kinetics of the dissolution process of carbonate rocks. Mutlutuk *et al.* (2004) found that the change in temperature can destroy the rock integrity through repeated cyclic freeze-thaw experiments, and the more times and higher frequency of freeze-thaw cycles are undergone, the greater the loss of rock integrity occurs, and the more obvious the characteristics of damage and destruction is. Ding *et al.* (2015) took the limestone from Longmen Grottoes in Luoyang as the research object, and carried out mechanical tests under the action of different hydrochemical solutions and freeze-thaw coupling with the consideration of the influence of the erosion of limestone seepage solution and freeze-thaw damage in winter. Yang *et al.* (2014) used diamond anvil cell (DAC) technology to conduct corrosion experiments, and concluded that with the increase of stratum temperature and pressure, limestone exhibits obvious cementation (sediment), and dolomite is not

more easily corroded than limestone under the conditions of acidic stratum fluid with a high temperature and high pressure. Temperature is an important factor that affects the dynamic mechanical properties of rocks and the internal structure of rocks will be damaged due to the temperature changes. After undergoing temperature changes, the strength and deformation of rocks have great changes, which will have a great impact on engineering structures.

Under the action of vibration load and stress, the primary pores, crack propagation and fracture of carbonate rocks will change the permeability, and the carbonate rocks show different characteristics in different stress-strain stages. Vital *et al.* (2016) studied the hydrodynamic problems in the concretion and dissolution processes of carbonate rocks in the southeast of Buenos Aires province, Argentina, and pointed out the influence of mineral particle size on hydrochemistry and the relationship between mineral structure changes and hydrodynamic pressure in the process of dissolution. Ma *et al.* (2013) carried out tests on seepage characteristics of fissuring rock masses under different confining pressures. The groundwater transported in rock cracks is affected by the width of cracks and their interconnection, and is also strictly controlled by the geometric shape and confining pressure conditions required by water flow. Ishibashi *et al.* (2013) discussed the seepage evolution of cracks in carbonate rocks caused by mechanical stress and non-equilibrium chemistry (pH value). According to the combination of constraint stress and liquid pH, pore spaces of cracks are either open (permeability increases) or closed (permeability decreases). Sheng *et al.* (2013) through designing experiments under different working conditions and with the condition of changing osmotic pressure and chemical solutions, acquired the change of fissure permeability under the action of stress, theoretically described the permeability characteristics of rock mass fissures under the seepage-stress-chemical coupling action, and further revealed the mechanism of the seepage-stress-chemical coupling action. Chen *et al.* (2011) reviewed the research status of thermal, water and mechanical properties of rock masses under low temperature and freeze-thaw cycle conditions, and put forward to establish a water-heat coupling model of rock masses with phase transition at low temperature and a turbulence model of tunnel airflow field by considering the

influence of air temperature and humidity by the means of field monitoring, a large number of indoor freeze-thaw tests, and uniaxial and triaxial compression tests.

To sum up, there are many researches focusing on the corrosion of dolomite and limestone under the action of chemistry, temperature and vibration load, but the existing chemical corrosions and researches in karst areas mainly focus on limestone-dominated areas or areas with miscellaneous lithology, so the study on corrosion in areas with dolomite-dominated lithology needs to be further strengthened. Scientific problems such as differential corrosion characteristics of rocks and identification of influencing factors in dolomite and limestone development areas have not been completely solved. Therefore, it is of great theoretical and practical significance to systematically carry out tests to determine the structural characteristics and differential corrosions of limestone and dolomite and explore the influencing mechanism of differences between dolomite and limestone on karst geologic disasters.

2. Test Samples

2.1. Collection and analysis of the test samples

Several limestone and dolomite samples were collected from large-scale construction sites such as highways, main roads and urban railway transits in Guilin and Liuzhou regions in the north of Guangxi. After returning to the laboratory, the representative samples were selected and analyzed for the minerals and structural characteristics of the rocks with an optical microscope, so as to roughly obtain the mineral composition, structural characteristics and name of the samples. The specific test results are shown in Table 1.

Table 1. Mineral composition and structural characteristics of limestone and dolomite test samples.

Sample No.	Macroscopic observation	Mineral composition	Structure construction	Name
1	The rock is in gray-white color, with a fine crystalline texture and massive structure. It bubbles slightly when dropping cold diluted HCl solution. It is mainly composed of carbonate minerals.	Dolomite: 97%; calcite: 2%; others: 1%	Fine crystalline texture, massive structure	Fine-grained dolomite

2	<p>The rock is in dark black color, with a powder crystalline texture and massive structure. The rock is so hard that a knife cannot strike on it. It bubbles strongly when dropping cold diluted HCl solution. It is mainly composed of carbonate minerals, carbonaceous matter, and siliceous matter.</p>	<p>Calcite: 85%; carbonaceous matter: 8%; siliceous matter: 7%</p>	<p>Fine crystalline texture, massive structure</p>	<p>Carbonaceous siliceous limestone</p>
3	<p>The rock is in gray-white color, with a fine crystalline texture and massive structure. It bubbles slightly when dropping cold diluted HCl solution. It is mainly composed of carbonate minerals.</p>	<p>Dolomite: 98%; calcite: 2%</p>	<p>Fine crystalline texture, massive structure</p>	<p>Fine-grained dolomite</p>
4	<p>The rock is in gray color, with an argillaceous texture and massive structure. The knife can strike on it. The rock powder has a slippery feeling. It is mainly composed of mud. It is in lamina and lamellation configuration. The minerals have a slightly oriented arrangement, but not obvious. A thin layer of pyrite is found in the hand specimen, which is granular aggregates and concentratedly distributed locally.</p>	<p>Dolomite: 98%; calcite: 2%.</p>	<p>Argillaceous texture, massive structure</p>	<p>Pyrite-bearing and sand-bearing mudstone</p>
5	<p>The rock is in gray color, with a powder crystalline to mesocrystalline texture and massive structure. It bubbles strongly when dropping cold diluted HCl solution. It is mainly composed of carbonate minerals. It fragments in later stage, with broken cracks in lattices interspersed.</p>	<p>Calcite: 98%; dolomite: 1%; others: 1%</p>	<p>Powder crystalline to mesocrystalline texture, massive structure</p>	<p>Mesocrystalline limestone</p>
6	<p>The rock is in gray-white color, with a fine crystalline texture and massive structure. It bubbles slightly when dropping cold</p>	<p>Dolomite: 97%; calcite: 2%; others: 1%</p>	<p>Fine crystalline texture, massive structure</p>	<p>Fine-grained dolomite</p>

	diluted HCl solution. It is mainly composed of carbonate minerals.		
7	The rock is in dark gray color, with a mesocrystalline texture and massive structure. It bubbles weakly when dropping cold diluted HCl solution. It is mainly composed of carbonate minerals. The rock is broken, with broken cracks interspersed.	Dolomite: 98%; calcite: 2%	Fine crystalline to mesocrystalline texture, massive structure Mesocrystalline dolomite
8	The rock is in black color, with a microcrystalline to powder crystalline texture and massive structure. It bubbles slightly when dropping cold diluted HCl solution. It is mainly composed of carbonate minerals and carbonaceous matter.	Dolomite: 40%; calcite: 55%; carbonaceous matter: 5%	Microcrystalline to powder crystalline texture, massive structure. Carbonaceous dolomite

2.2. Description of characteristics of the test samples

In the process of mineral and rock identification, it is difficult to accurately judge the mineral and rock only by naked eyes and simple tools for some fine-grained, micro-grained, aphanitic or vitreous rocks; so it is necessary to triturate the 0.03 mm thick rock or mineral slices and identify with the aid of an optical microscope. The transmission polarizing microscope is used for identification of transparent minerals, while the reflection polarizing microscope is used for identification of opaque minerals. The test samples shown in Table 1 are photographed with an optical microscope and further described in details below.

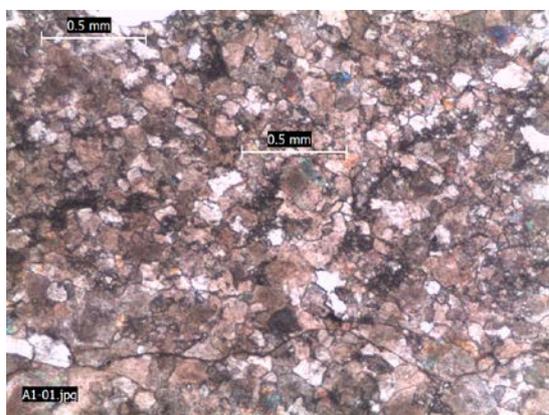

Photo 1

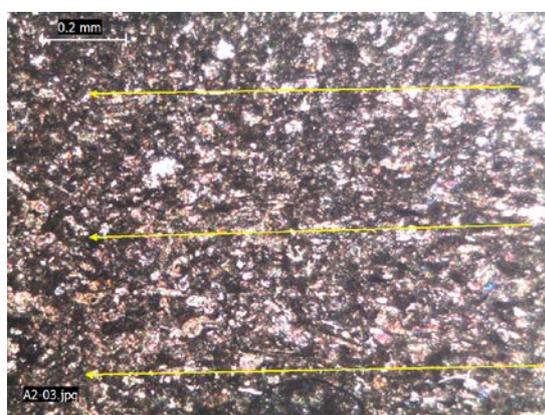

Photo 2

Test sample No. 1: The rock has a fine crystalline texture. The rock is composed of 0.06-0.25 mm dolomite. The dolomite is in irregular particles with poor automorphic degree, and the particles are closely embedded into aggregates (Photo 1). The dolomite is not colored with the alizarin red staining. The rock contains 2% calcite, 97% dolomite, and <1% others.

Test sample No. 2: The rock has a fine crystalline texture. The rock is mainly composed of 0.03-0.06 mm calcite and a small amount of carbonaceous and siliceous minerals (Photo 2). The rock contains 85% calcite, 8% carbonaceous mineral, and 7% siliceous mineral. The calcite is colored with the alizarin red staining, and its content is about 85%. The rock minerals are slightly oriented.

Photo 3

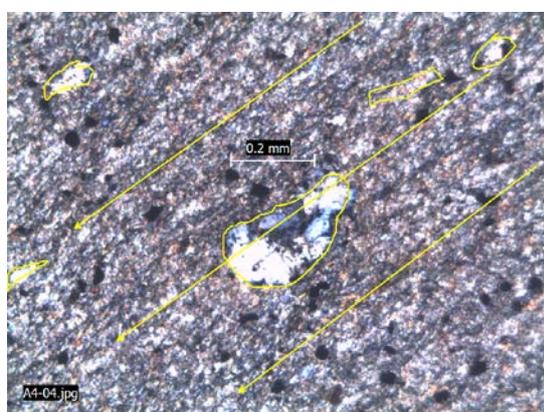

Photo 4

Test sample No. 3: The rock has a fine crystalline texture. The rock is composed of 0.06-0.25 mm dolomite. The dolomite is in irregular particles with poor automorphic degree (rhombus is found locally). The particles are closely embedded into aggregates (Photo 3). The dolomite is not colored with the alizarin red staining. The rock contains 98% dolomite and 2% calcite.

Test sample No. 4: The rock has an argillaceous texture. The rock is mainly composed of clay minerals, a small amount of quartz sand and a small amount of granular pyrite. The rock contains about 90% clay minerals, about 5% quartz sand and about 5% pyrite, with quartz sand and pyrite scattered (Photo 4). Sandy grains vary from 0.05-0.20 mm, and are mostly sub-round. Pyrite is opaque (photo 5), with a size of 0.02-0.04 mm. Minerals are in oriented arrangement, but not obvious.

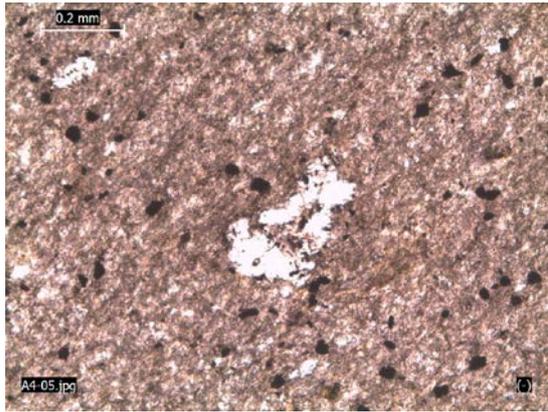

Photo 5

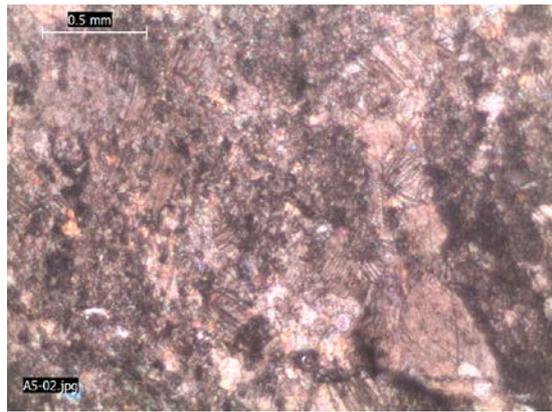

Photo 6

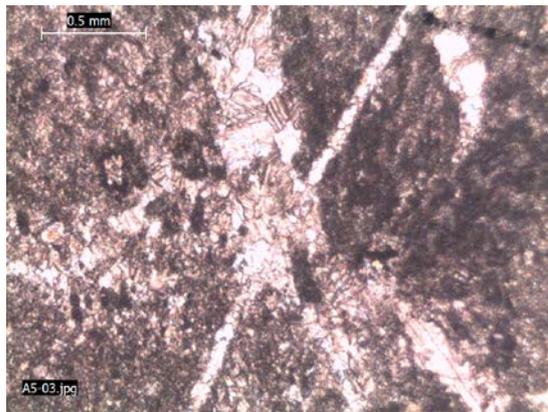

Photo 7

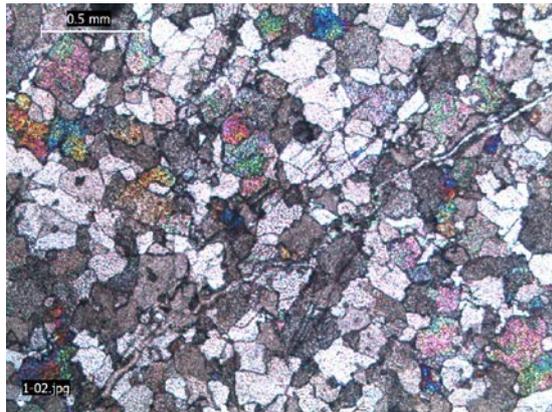

Photo 8

Test sample No. 5: The rock has a powder crystalline to mesocrystalline texture (Photo 6). The rock is mainly composed of 0.03-0.50 mm calcite minerals. The calcite is irregularly granular, in rhombohedron, rhombic cleavage, high-grade white interference color, and 0.03-0.50 mm in size, of which over 80% is in the range of 0.25-0.50 mm. The calcite is in red and the dolomite is not colored when the rock is dyed with alizarin red. The rock contains 98% calcite, 1% dolomite, and <1% other organic matters. In the later stage, the broken cracks are interspersed and filled with calcite (Photo 7).

Test sample No. 6: The rock has a fine crystalline texture. The rock is composed of 0.05-0.25 mm dolomite, of which more than 95% is in the range of 0.06-0.25 mm. The dolomite is in irregular particles with poor automorphic degree. The particles are closely embedded into aggregates (Photo 8). The dolomite is not colored with the alizarin red staining. The rock contains 2%, 97% dolomite, and <1% others. In the later stage, the cracks are filled with calcite.

Test sample No. 7: The rock has a fine crystalline and mesocrystalline texture. The rock is mainly composed of 0.05-0.50 mm dolomite minerals (Photos 9 and 10),

of which 15% is in the range of 0.05-0.25 mm and 85% is in the range of 0.25-0.50 mm. Only the calcite filled in the cracks is colored with the alizarin red staining, with a content of about 2% (Photo 10). The remaining is mainly dolomite with a content of about 98%.

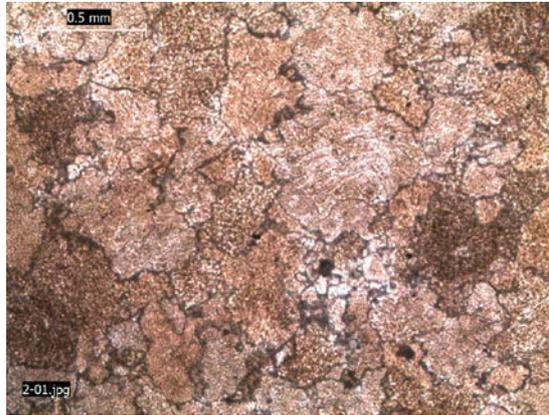

Photo 9

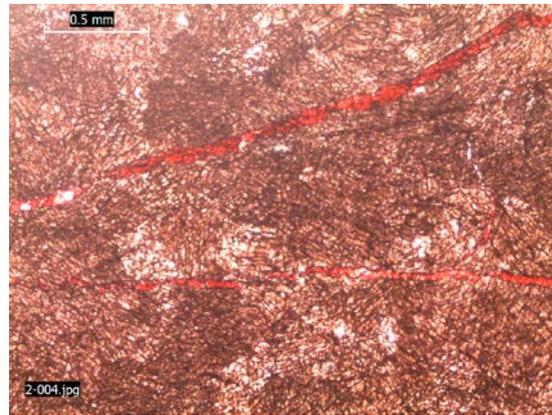

Photo 10

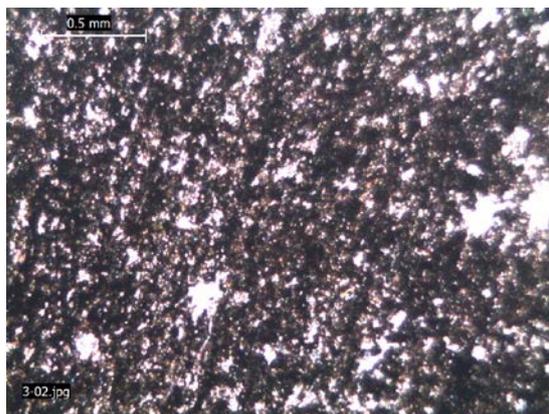

Photo 11

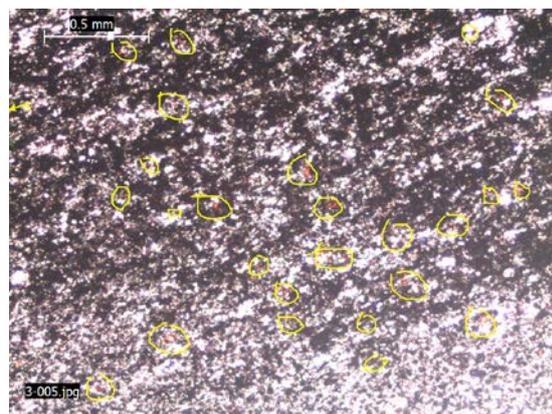

Photo 12

Test sample No. 8: The rock has a microcrystalline to powder crystalline texture, and is mainly composed of dolomite, calcite and opaque carbonaceous mineral. The mineral particle size is mainly between 0.005-0.10 mm, of which more than 70% is in the range of 0.03-0.06 mm. The rock is dyed with alizarin red, and contains about 40% calcite, about 55% dolomite, and 5% carbonaceous mineral and others (Photos 11 and 12). The calcite is irregularly granular, with high-grade white interference color, and is evenly distributed in the rock. The dolomite is irregularly granular, with a particle size of 0.05-0.10 mm.

2.3. Chemical composition analysis of the test samples

As shown in Table 1, the above description that the test samples taken in the

experiments are mainly crystalline dolomites and limestones with high purity (except for the test sample No. 4). The test samples with good appearance and characters other than the test sample No. 4 were select, and detected for the amounts of CaO, MgO, CO₂, SiO₂, acid insoluble matter, and loss on ignition by using high-frequency infrared sulfur-carbon analyzer and X-ray fluorescence spectrometer, respectively. The specific test results are shown in Table 2. Then the ratio of CaO/MgO was calculated to judge the purity of dolomite and limestone(Zeng,1986; Zhu, 2008). Among them, dolomite and limestone with high purity were selected, and then the subsequent corrosion tests were carried out.

Table 2. List of chemical composition analysis of dolomite and limestone test samples.

sample No.	field naming	chemical composition of dolomite and limestone samples(%)						
		CaO	MgO	SiO ₂	LOSS	acid insoluble matter	CO ₂	CaO/MgO

3. Corrosion Tests

The corrosion (corrodibility) of water is an internal factor of water-rock interaction, and the mobilization property and chemical characteristics of water will inevitably affect the characteristics of action of water on carbonate rocks. The main acidic fluids of dolomite and limestone corrosion in the actual field environment are the aqueous solutions of CO₂, organic acids and H₂S. However, in the indoor simulation tests, the acidity of carbonic acid solution is weak, and its reaction with limestone and dolomite is slow under static conditions. When calcium chloride or solution containing calcium ions is added to the aqueous solution of organic acids, insoluble calcium salt precipitate can be formed. H₂S gas is toxic. In acidic solutions commonly used in laboratories, SO₄²⁻ in sulfuric acid solution will react with the

corroded Ca^{2+} and Mg^{2+} to generate slightly soluble substances and insoluble substances, which will affect the determination of Ca^{2+} and Mg^{2+} . At the same time, due to the fairly long reaction process between the ions in groundwater and the minerals in rocks in nature, it is difficult to obtain ideal test results under limited time and conditions, so hydrochloric acid solution at pH 3.0 was specially prepared for the indoor accelerated corrosion tests.

3.1. Comparison of the static corrosion test results between dolomite and limestone under the same conditions

All the devices used in this experiment are self-designed, and the experimental devices mainly include thermostat, vibration equipment, pH measuring instrument, measuring equipment for Ca^{2+} and Mg^{2+} , and related chemicals and reagents, *etc.* The thermostat can keep the experimental environment at a stable temperature all the time and reduce the influence caused by the external environment. A constant speed stirrer is mounted at the bottom of the thermostat, which makes the solution flow through the rotation at a constant speed, thus simulating the outdoor hydrodynamic conditions.

In order to reduce the discreteness of the test samples, the rock samples taken for the experiment were made into cylindrical slices, and the pulsed ultrasonic penetration method was used to detect and screen the samples, from which the rock samples with similar wave velocities were selected. The specific experimental steps are as follows: (i) measuring the diameter, height of the rock samples by vernier caliper and weighing the rock samples (Table 3), and calculating the parameters such as surface area, volume and density, *etc.*; (ii) washing the test samples with distilled water, drying them in an oven, cooling in a dryer to room temperature, and weighing; (iii) adding 5 L hydrochloric acid solution at pH 3.0 into a clean beaker, and adding the rock samples successively; (iii) standing at room temperature, removing the corroded liquid every 2 hours, and measuring the concentration of calcium and magnesium ions in the solution by ethylene diamine tetraacetic acid (EDTA) solution titration method; (iv) calculating the corrosion amount of the rock samples. In order to eliminate the influence of surface area differences of the rock samples, the results of this experiment are expressed by the corrosion amount per unit surface area.

Table 3. List of parameters and corrosion results of limestone and dolomite test samples.

sample No.	lithology	weight g	diameter mm	height mm	surface area mm ²	volume mm ³	density g/ cm ³	corrosion amount mg	corrosion amount per unit area mg/ mm ²
1-14	dolomite	120.81	68.87	12.21	10087.07	45461.68	2.66	3583.01	0.355
3-6	dolomite	115.27	69.25	11.54	10038.35	43442.52	2.65	3473.27	0.327
2-10	limestone	127.23	70.58	12.69	10633.39	49624.32	2.56	3293.24	0.328

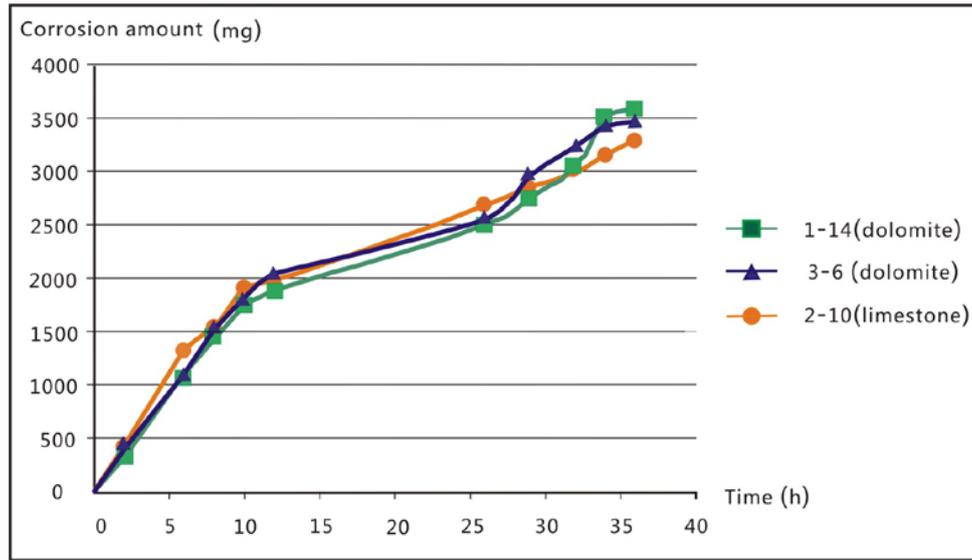

Fig. 1 Comparison of corrosion test results of dolomite and limestone under the same conditions.

As shown in Fig. 1, the corrosion rates of dolomite and limestone are basically the same under static conditions, and the corrosion amount per unit surface area for dolomite is 0.341 mg (average value), which is slightly larger than that of limestone (0.328 mg). And there is little difference between them for a long time.

3.2. Comparison of dolomite test results under different conditions.

Temperature is one of the important factors affecting the mechanical properties of rocks. Rock is composed of solid mineral particles and tiny gaps between the mineral particles. The solid mineral particles and the channel networks formed by the gaps between the mineral particles are often filled with fluid media. When the environment of such porous media of the rock changes, the water existing in the pores and fissures inside the rock would undergo phase change, which leads to changes in the physical and mechanical properties of the rock. These changes are not only related

to the physical structure, but also affected by the existing water, temperature and stress state of the rock. At the same time, under the action of vibration load and stress, the primary pores, crack propagation and fracture of dolomite and limestone cause the permeability to change, and then the dolomite and limestone exhibits different characteristics in different stress-strain stages. In order to study the influence of temperature and vibration load on the corrosions of dolomite and limestone, a group of dolomite and limestone were specially selected (the specifications and size of the samples are shown in Table 4), and the corrosion tests were carried out at different temperatures (0°C and 40°C) and vibration conditions. The corrosion results of the selected samples under different conditions are shown in Table 4 and Fig.2.

Table 4. List of parameters and corrosion results of limestone and dolomite samples.

sample No.	lithology	weight g	diameter mm	height mm	surface area mm ²	volume mm ³	density g/cm ³	corrosion amount mg	corrosion amount per unit area mg/mm ²
4-7		119.45	68.50	12.26	10003.84	45158.68	2.65	2246.13	0.225

1-11		124.48	68.74	12.71	10161.92	47144.85	2.64	4604.62	0.456

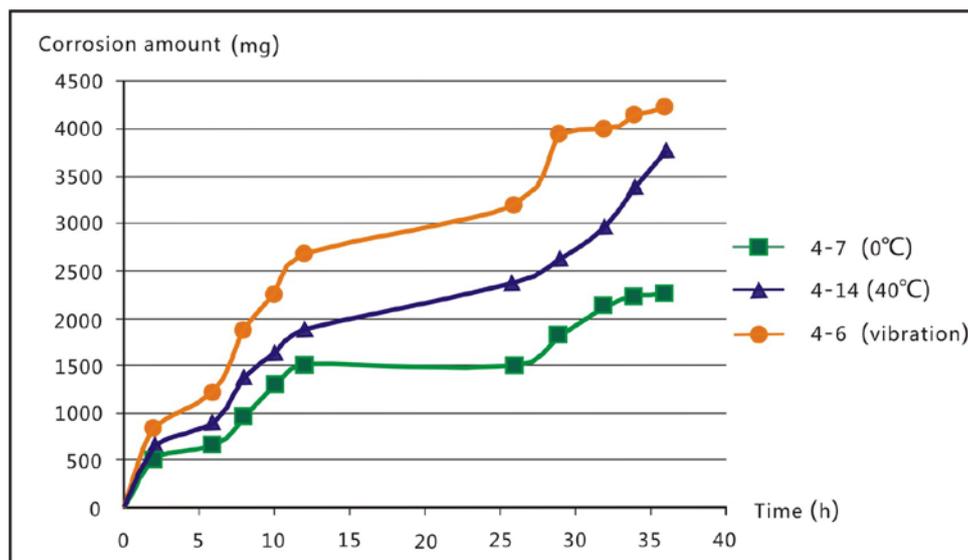

Fig. 2 Comparison of the corrosion test results of dolomite under different conditions.

As shown in Fig.2, the corrosion rate of dolomite is the lowest at 0°C, and is increased at 40°C, but the difference is not significant. However, the corrosion rate and amount of dolomite are increased significantly under the vibration condition, and the corrosion rate under the vibration condition is about 1.75 times of the corrosion rate at 0°C. The results indicate that vibration load has a more significant effect on the corrosion rate of dolomite than temperature.

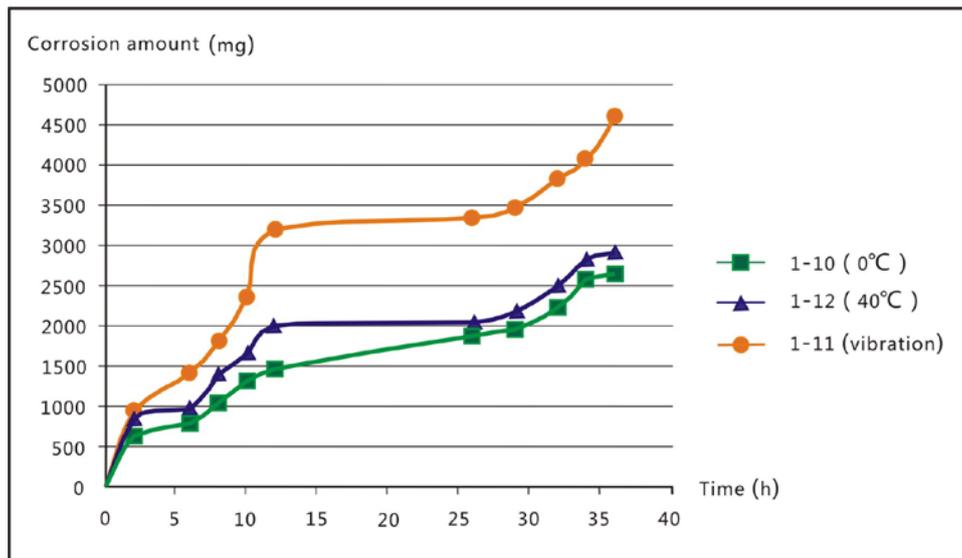

Fig.3 Comparison of the corrosion test results of limestone under different conditions.

As shown in Fig.3, the corrosion rate of limestone is the lowest at 0 °C, and the corrosion amount is increased at 40 °C, and the variation amplitude of limestone is larger than that of dolomite. At the same time, the corrosion rate and amount of limestone under the vibration load is also increased significantly, and the corrosion rate under the vibration load is about 1.88 times of the corrosion rate at 0 °C. The results demonstrate that the corrosion rate of limestone is highly sensitive to both temperature and vibration load.

4. Analysis and discussion of the test results

The corrosion of erosive aqueous solution is an internal factor of water-rock interaction, and the mobilization property and chemical characteristics of water affect the characteristics of the action of erosive aqueous solution on dolomite and limestone. With the progress of water-rock interaction, the change of internal structure and pore characteristics of rock would inevitably lead to the unceasing change of groundwater seepage field. At the same time, the hydrochemical property in the rock mass also

changes correspondingly, which is mainly reflected in the coupling process of chemical field, temperature field and stress field of water-rock interaction.

The dolomite (from Liuzhou area) selected in this study has a CaO/MgO ratio of less than 2.2, an acid insoluble content between 0.31%-0.68%, and a SiO₂ content between 0.24%-1.32%, so it belongs to a pure dolomite. The selected limestone (from Guilin area) has a CaO/MgO ratio of greater than 10, and the contents of acid insoluble matter and SiO₂ are generally higher, and the purity is slightly lower. In the pure carbonate rocks, the corrosion rate of calcite is generally higher than that of dolomite, and the corrosion rate increases with the increase of calcite content and decreases with the increase of dolomite content. In the impure carbonate rocks, due to the increase of acid insoluble matters and SiO₂ content, the amount of physical damage is increased, which inhibits the relationship between the corrosion rate and the calcite and dolomite content. Similarly, the structure of rock also has a certain influence on the corrosion rate. Generally speaking, the smaller the grain size, the larger the specific surface area, and the faster the corrosion rate. Therefore, in this study, the corrosion rates of dolomite and limestone are basically the same under the same conditions. However, under the influence of different temperatures and vibration loads, the corrosion rates of dolomite and limestone are somewhat different.

Temperature is one of the important factors affecting the properties of dolomite and limestone. In fact, the corrosion process of dolomite and limestone is a process in which ions in the lattice of carbonate minerals leave their original positions and transfer into water under the influence of electric charge and thermodynamic conditions of the polar molecules in the erosive water. In the surface environment, this process involves a three-phase complex system of gas, liquid and solid, and their chemical reactions are influenced by many factors, such as pH, temperature, hydrodynamic conditions, specific surface area of minerals, genesis structure of minerals, external vibration load conditions, *etc.* In northern Guangxi, the solar radiation is intense, the average sunshine time is long, and the rock surface heats up quickly and cools down slowly, which has a significant heating effect. Rock surface and earth surface temperature can reflect the water-heat exchange process of earth surface, which has a certain influence on the corrosion rate of carbonate rocks. In

northern Guangxi, the corrosion amount per unit surface area is 0.267 mg/mm^2 for dolomite, and 0.225 mg/mm^2 for limestone at 0°C . The corrosion amount per unit surface area is 0.287 mg/mm^2 for dolomite, and 0.375 mg/mm^2 for limestone at 40°C . The corrosion rate of both dolomite and limestone increases with the increase of the experimental temperature, and the increasing amplitude for limestone is larger than that for dolomite. This is possibly because the dolomite has more pores on the surface, and mostly has stratification structures, and is easily to form corrosion films and pores on the surface, while the limestone has fine mineral particles (microcrystalline to powder crystalline), has compact structures, and is more conducive to the surface corrosion with the increase of temperature.

Corrosion includes chemical dissolution and mechanical damage, and vibration load is one of causes for mechanical damage. With the rapid development of economy and society and the adjustment of national strategy, more and more high-speed railways and highways need to pass through the karst areas in northern Guangxi. In the process of construction and operation, the influence of vibration loads such as vehicles (especially high-speed trains and urban railway transits) is more conducive to increasing the corrosion rate of dolomite and limestone, especially obvious in the districts with better hydrodynamic conditions. Vibration loads will aggravate the degree of chemical corrosion of water on the rocks, and the coupling of mechanical destruction and chemical corrosion will lead to the generation of secondary minerals and secondary pores in the rocks, which will accelerate the rate of corrosion reaction. The corrosion rate of dolomite in northern Guangxi is increased significantly under the vibration load conditions, which is about 1.75 times of that at 0°C . The corrosion rate of limestone is also increased significantly, which is about 1.88 times of that at 0°C . Under the action of vibration load, physical disintegration is dominant in the corrosion process of dolomite, and the rock fragments provided by physical disintegration are more conducive to chemical corrosion. In addition, the uniform intercrystalline pores in dolomite are beneficial to the overall corrosion. However, the distribution of fissuring gaps is extremely uneven when the limestone is stressed, and thus the limestone is easy to form rock cracks and cave systems, which is characterized by obvious differential corrosion.

5. Conclusions

(1) The dolomite in northern Guangxi mainly has a fine crystalline texture and massive structure, and the ratio of CaO/MgO is generally less than 2.2. The dolomite has high purity. The limestone mainly has a powder crystalline texture and massive structure. The ratio of CaO/MgO is generally greater than 10, and the highest ratio can reach about 140. The limestone also has high purity. The content of acid insoluble matter is low in dolomite, but is high in limestone due to the high content of carbonaceous matter.

(2) The corrosion of dolomite and limestone mainly depends on the chemical composition of rocks, the structure of rocks and minerals, the ratio of different mineral components, seepage conditions and other factors. The difference of corrosion between dolomite and limestone mainly depends on the ratio of CaO/MgO in their chemical composition, and only when the acid insoluble matter exceeds 10% will the corrosion amount be substantially affected.

(3) Under the same external conditions, the corrosion rates of the pure dolomite and the pure limestone are basically the same. The corrosion amount per unit surface area is 0.341 mg for dolomite, and 0.328 mg for limestone. The corrosion amount per unit surface area of dolomite is slightly larger than that of limestone.

(4) The corrosion rates of dolomite and limestone are largely influenced by temperature and vibration load. The corrosion rates of dolomite and limestone are low at 0 °C and are increased with the increase of temperature, but the influence of vibration load on corrosion rate is more significant than temperature.
