Research article

Abstract

Background: Intravenous thrombolysis (IVT) is a rapid and effective treatment in the early stage of ischemic stroke patients and the purpose of this work is to explore the significance of Hounsfield unit(HU) value in Alberta Stroke Program Early CT Score (ASPECTS) for predicting the clinical prognosis of stroke patients with middle cerebral artery occlusion (MCAO) treated by IVT.

Methods: The 84 stroke patients with MCAO treated by IVT were divided into good prognosis group (48 cases) and poor prognosis group (36 cases). HU ratio and HU difference calculated from non-contrast computed tomography (NCCT) between groups were analyzed.

Results: The HU ratio of good prognosis group was higher than that in poor prognosis group and the HU difference of good prognosis group was lower than that in poor prognosis group ($P<0.05$). The HU ratio was negatively correlated with the infarct volume, and the HU difference was positively correlated with the infarct volume ($P<0.05$). HU difference was an independent risk factor for prognosis of patients with MCAO treated by IVT. The area under the curve (AUC) of HU ratio and HU difference for prognosis was 0.743 and 0.833 respectively ($P<0.05$).

Conclusion: The HU value changes are related to the clinical prognosis of stroke patients with MCAO treated by IVT, HU value may be a prognostic indicator for stroke patients with MCAO treated by IVT.

Background

Intravenous thrombolysis (IVT) is a rapid and effective treatment in the early stage of ischemic stroke patients, which can restore blood flow, improve cerebral blood circulation, and improve the clinical prognosis of patients. However, the efficacy of IVT in different patients is significant different, and their clinical outcomes are different. Previous studies have shown that patients with higher Alberta Stroke Program Early CT Score (ASPECTS) usually have better clinical outcomes and a lower risk of symptomatic intracranial hemorrhage[1-3].

ASPECTS is a scoring method that can be used to evaluate early ischemic changes in the middle cerebral artery blood supply area. ASPECTS can be obtained on CT scan. This method is simple and easy to use, and is widely used by many stroke centers. However, stroke patients treated with IVT are in the hyperacute stage of stroke, and their head CT images change very slight, and the consistency and accuracy of ASPECTS are questioned due to subjective differences of observers[1].

The HU value reflects the water uptake of the infarcted tissue. As the water uptake increases, the HU value decreases. HU value can reflect the length of infarction time and can be used to judge the stroke time of the patients [4, 5]. Previous studies have shown that HU value from non-contrast computed tomography (NCCT) in ASPECTS helps to identify the core of infarction and is related to the final infarct volume of stroke after IVT[6, 7]. Therefore, this research aimed to explore the significance of HU value in ASPECTS

for predicting the clinical prognosis of stroke patients with middle cerebral artery occlusion (MCAO) treated by IVT.

Methods

Patients

Eighty-four stroke patients with MCAO in our hospital who received IVT from January 2018 to December 2019 were retrospectively analyzed. The 84 stroke patients were divided into good prognosis group (48 cases) and poor prognosis group (36 cases). Inclusion criteria: ⓵ age ≥ 18 years old; ⓶ patients who arrived at the hospital within 6 hours after stroke onset and received IVT; ⓷stroke patient with MCAO was diagnosed by MRI images within 7 days after IVT; ⓸complete patient clinical data. Exclusion criteria: ⓵poor CT image quality; ⓶patients with bilateral infarction. This study was approved by the Research Ethics Committee of the Second Affiliated Hospital of Nantong University. The severity of stroke at admission was evaluated using National Institute of Health stroke scale (NIHSS). The clinical prognosis at 3 months after thrombolysis were evaluated using the modified Rankin Scale (mRS). According to mRS, the 84 stroke patients were divided into good prognosis group (0~2, 48 cases) and poor prognosis group (3~6, 36 cases). The clinical data of patients was showed in the Table-1.

Image analysis

Head scan was performed with Seimens FORCE CT. Scanning position: supine position; scanning positioning reference line: orbito-meatal line (OML); scanning parameter setting: tube voltage was 100 KV, tube current was 120 mA, and layer thickness was 2 mm.

Two radiologists with more than 5 years of neuroimaging diagnosis experience who were blinded to the clinical data measured the NCCT images. Ten ASPECTS regions were manually outlined on the NCCT images (Fig.1) and the HU values were calculated. The HU value of each ASPECTS area of the infarct side cerebral hemisphere was divided by the HU value of the corresponding ASPECTS area of the healthy side cerebral hemisphere to obtain the HU ratio. The HU value of each ASPECTS area in the infarcted side cerebral hemisphere was subtracted from the HU value of the corresponding ASPECTS area of the healthy hemisphere to obtain the HU difference.

Patient with hemorrhagic transformation was defined as hemorrhage found on MRI images within 7 days after thrombolytic therapy. The patient's cerebral infarct volume was calculated on the DWI image within 7 days after thrombolytic therapy.

Statistical analysis

The measurement data was expressed by mean±SD or median, and the count data was expressed by percentage. The KS test was used to determine whether the data was normally distributed. The normal distribution data was analyzed with t test. Mann-Whitney U test was used to analyze non-normally distributed data. Spearman correlation analysis was used to evaluate the relationship between HU

ratio/HU difference and infarct volume. The factors such as age, gender, initial NIHSS, ASPECTS, hyperdense middle cerebral artery sign (HMCAS), lenticular nucleus obscuration (LNO) and HU ratio or HU difference were taken into the Binomial Logistic regression equation. The area under the ROC curve (AUC) was used to evaluate the diagnostic efficacy of ASPECTS, HU ratio and HU difference for the prognosis of stroke patients with MCAO treated by IVT. P value <0.05 was considered statistically significant. All data were performed by SPSS 25.0 (IBM. Corp., Armonk, NY, USA) and MedCalc (MedCalc, Mariakerke, Belgium).

Results

Comparison of clinical features between the two groups

By comparing the good prognosis group with the poor prognosis group, we found that the good prognosis group had lower admission NIHSS score and higher ASPECTS (P 0.05). The good prognosis group had a smaller infarct volume (P 0.05). The good prognosis group has a lower risk of hemorrhagic transformation (P 0.05). We found that the HU ratio and HU difference between the two groups were significantly different. The good prognosis group had a higher HU ratio and a lower HU difference (P 0.05). In addition, our study also found that early image signs of NCCT (HMCAS and LNO) were associated with the prognosis of thrombolytic patients. The detailed results were shown in Table-1.

The relationship between HU ratio/HU difference and infarct volume

The HU ratio was negatively correlated with the infarct volume, and the HU difference was positively correlated with the infarct volume (P 0.05). The detailed results were shown in Table-2.

Independent risk factors for prognosis of stroke patients with MCAO treated by IVT

The factors such as age, gender, initial NIHSS, ASPECTS, HMCAS, LNO and HU ratio or HU difference were taken into the Binomial Logistic regression equation. The results showed the initial NIHSS, ASPECTS and HU difference was independent risk factors for prognosis of stroke patients with MCAO treated by IVT (P 0.05). The detailed results were shown in Table-3, 4.

Diagnostic efficacy for the prognosis of stroke patients with MCAO treated by IVT

The ROC curve showed that AUC of ASPECTS, HU ratio, HU difference were 0.762, 0.743 and 0.833, which were meaningful to predict the prognosis of patients (P 0.05). The AUC of the HU difference was greater than that of ASPECTS and HU ratio, but no statistical significance was found (P 0.05) (Fig.2). The detailed results were shown in Table-5.

Discussion

Our research found that the changes in HU value of ASPECTS were related to the clinical prognosis of stroke patients with MCAO treated by IVT. HU difference was the independent risk factor for prognosis of

stroke patients with MCAO treated by IVT. The changes in HU value can be used to predict the clinical prognosis of stroke patients with MCAO treated by IVT. HU value measurement can help clinicians make quick decisions and select potential beneficiaries of IVT.

Our research found that the HU ratio of the good prognosis group was higher than that of the poor prognosis group, and the HU difference was lower than that of the poor prognosis group. This may be because the decrease in HU value is significantly related to the increase in water content of ischemic brain tissue. It was reported that increasing the water content of the cerebral hemisphere by 1% will cause the HU value to decrease by 1.8 HU. Water uptake content of infarcted brain tissue was related to the degree of infarction[8, 9]. Our research found the HU ratio was negatively correlated with the infarct volume, and the HU difference was positively correlated with the infarct volume. Smaller HU ratio and larger HU difference were related to larger infarct volume. HU value is also related to the state of cerebral blood flow. Kucinski et al[10] reported that within 4.5 hours after the onset of stroke, the decrease in HU value was related to the decrease in cerebral blood flow and volume. In the hyperacute phase of stroke, the HU value changes very slightly. Compared with CTP and MRI, NCCT is difficult to accurately delineate the infarct range and measure the HU value. However, for stroke centers without advanced imaging techniques such as CTP and MRI, NCCT is still the preferred imaging examination before thrombolytic therapy. In order to overcome this difficulty, we selected 10 ASPECT regions to measure HU values in stroke patients with MCAO. For the hyperacute phase of stroke, NCCT can detect brain tissue swelling and gray matter lesions in time. NCCT has the advantages of fast imaging speed, low price and wide popularity. NCCT does not require contrast injection and will not cause adverse reactions. Our study also found that early image signs of NCCT (hyperdense middle cerebral artery sign, lenticular nucleus obscuration) were associated with the prognosis of thrombolytic patients, which is consistent with previous studies[11-13].

The ASPECTS is a scoring system for evaluating early ischemic changes in the blood supply area of the middle cerebral artery by NCCT. It is essentially based on visually low attenuation. In addition, the ASPECTS is time-dependent, and a study shown that the reliability of ASPECTS is moderate at stroke onset time⬚90 min, good at 90-180 min, and excellent at >180 min. The HU value is based on the attenuation coefficient of water to calculate the HU value of each tissue[14], which is quantitative in nature, and the measurement of HU value is independent of the subjective interpretation of any observer. Compared with the ASPECTS, the reliability and consistency of the HU value are greatly improved. In this study, two patients had the same ASPECTS, but their HU values changed differently, and their clinical outcomes were different (see Fig.3, Fig.4). The ROC curve showed that the AUC of the HU ratio was 0.743, when the cutoff value was 10, it had a higher sensitivity of 80.56%. The AUC of the HU difference was 0.833, when the cutoff value was 13.97, it had a higher specificity of 93.75%. The results indicated that the HU ratio and HU difference had important predictive value for the prognosis of stroke patients treated by IVT. For stroke patients with the same ASPECTS, the HU value can be used for a second evaluation to improve the accuracy of diagnosis. In the future, more research is needed to perfect this algorithm to improve the predictive value of HU. Our study has some limitations: ⬚The influence from the occlusion position on the patient was not taken into account, for stroke patients with a distant occlusion position,

the infarct size was too small, and the HU value did not change significantly. ⬚Previous study shown that the weight of each area of ASPECTS was different[15]. We did not weight each area when caculated the HU ratio or HU difference. ⬚The sample size was small. ⬚No subgroup analysis based on ASPECTS. ⬚Ten ASPECTS regions were manually outlined and maybe there is an deviation.

Conclusion

In summary, the HU value changes are related to the clinical prognosis of stroke patients with MCAO treated by IVT, HU value may be a prognostic indicator for stroke patients with MCAO treated by IVT.

Declarations

Ethics approval and consent to participate

This study was approved by the Research Ethics Committee of the Second Affiliated Hospital of Nantong University. Due to the retrospective nature of the study, informed consent was waived.

Consent for publication

The consent for publication has been obtained from the patients.

Availability of data and materials

The datasets used during the current study are available from the corresponding author on reasonable request.

Competing interests

The authors declare that they have no conflict of interest.

Authors' contributions

All authors contributed to the study conception and design. Material preparation, data collection and analysis were performed by ZZ, RZ, KR, RC, XZ, LZ, TW. The first draft of the manuscript was written by ZZ and all authors commented on previous versions of the manuscript. All authors read and approved the final manuscript.
